G 88ls
v.1
1882

TO

THE NUMEROUS PUPILS

WHO, DURING NEARLY HALF A CENTURY,

ATTENDED HIS LECTURES,

AND WHO ARE NOW SETTLED IN EVERY SECTION OF THE UNITED STATES, AS WELL AS

IN MANY FOREIGN LANDS,

IN THE

HONORABLE PURSUIT OF THEIR PROFESSION,

𝕿𝖍𝖊𝖘𝖊 𝖁𝖔𝖑𝖚𝖒𝖊𝖘,

DESIGNED TO ILLUSTRATE ONE OF THE MOST IMPORTANT AND VALUABLE BRANCHES OF
THE HEALING ART,

ARE RESPECTFULLY AND AFFECTIONATELY INSCRIBED

BY THEIR FRIEND,

THE AUTHOR.

A certis potius et exploratis petendum esse præsidium; id est, his quæ experientia in ipsis curationibus docuerit; sicut in cæteris omnibus artibus; nam ne agricolam quidem aut gubernatorem disputatione, sed usu, fieri.   CELSUS.

He—the surgeon—should be courteous and condescending, bold in security, cautious in time of danger, avoiding impracticabilities, compassionate to the infirm, benevolent to his associates, circumspect in his prognostication, chaste, sober, pious, and merciful, not greedy of gain, no extortioner, but looking to his fee in moderation, according to the extent of his services, the ability of his patient, the result of his treatment, and a proper sense of his own dignity.

GUY DE CHAULIAC.

We may not only rank Chirurgery among the Sciences; but look on it as one of the noblest, most certain, and most necessary of them all.   DIONIS.

The nobility and dignity of Chirurgery are too well known to want the help of an oratour to set them forth. If a panegyrick were necessary, it were best made by running through the particulars of the art, and the history of the diseases cured thereby.   WISEMAN.

PREFACE.

The object of this work, as set forth in the first edition, issued in 1859, is to furnish a systematic and comprehensive treatise on the art and science of surgery, considered in the broadest sense; one that shall serve the practitioner as a faithful and available guide in his daily routine of duty. My aim has been to embrace the whole domain of surgery, and to allot to every subject its legitimate claim to.notice in the great family of external diseases and accidents. If a larger space than is customary has been devoted to the consideration of inflammation and its effects, or the great principles of surgery, it is because of my conviction, founded upon long and close observation, that there are no subjects so little understood by the general practitioner. Special attention has also been bestowed upon the discrimination of diseases; and an elaborate chapter on general diagnosis has been introduced.

The work, although presented, as its title indicates, as a formal and systematic treatise, is founded upon the courses of lectures which it devolved upon me to deliver during the last forty-two years; first in the University of Louisville, for a long time the most flourishing medical school in the Southwest, and during the last twenty-six years in the Jefferson Medical College, from which, in 1828, I received my degree. During all that period, I was unceasingly devoted to the duties of an arduous practice, both private and public; to the study of the great masters of the art and science of medicine and surgery; and to the composition of various monographs which had a direct bearing upon a number of the subjects discussed in these volumes. The work should, therefore, be regarded as embodying the results of a large personal, as well as of a ripe, experience, of extensive reading, and of much reflection; in a word, as exhibiting surgery as I myself understand it, and as I, for so many years, conscientiously taught it.

The favor with which the work has been received is sufficiently attested by the exhaustion of five large editions, by its translation into the Dutch language, and by the universal commendation bestowed upon it by the periodical press, both at home and abroad. This evidence, so gratifying to my feelings as an author, instead of abating my ardor, has only served to stimulate me to

increased exertion to render the work still more useful as a faithful exponent of the existing state of the art and science of surgery.

Upon the edition now issued much time and labor have been expended, rendered necessary by the astonishing progress made during the last ten years in every branch of surgery. Every chapter has been thoroughly revised, many portions have been entirely rewritten, and a large amount of new matter has been introduced, in order to place the work fully abreast of the existing state of our knowledge. To impart completeness to my labors, in every respect most arduous and perplexing, I have freely availed myself of the assistance of Professor S. W. Gross, whose pen and judgment have been of the greatest service to me in supplying deficiencies, especially in relation to morbid growths, in collecting statistics, and in correcting the press. To Dr. J. Solis Cohen, Dr. George C. Harlan, and Dr. Charles H. Burnett my thanks are due for aid received in revising, respectively, the chapters on the Respiratory Organs, the Eye, and the Ear. The section on Refraction and Accommodation of the Eye, written for the fifth edition by Dr. William Thomson, Professor of Ophthalmic Surgery in the Jefferson Medical College, is retained nearly in its entirety. Professor Edward C. Seguin, of New York, has kindly furnished the section on Cranio-Cerebral Topography, the first attempt, as far as I know, to introduce matter of this kind into a work on surgery. Dr. Battey has kindly supplied me with valuable matter relative to Oöphorectomy, and Dr. Lewis Hall Sayre relative to the application of the plaster-jacket in the treatment of spinal diseases. To Dr. Barnes, late Surgeon-General of the United States Army, I am under obligations for many of the cuts which illustrate the subject of Gunshot Wounds. The elaborate index has been kindly prepared by Dr. Richard J. Dunglison, whose labors in the interests of American medical literature are so well known.

Of the engravings which accompany the volumes upwards of six hundred are original. The remainder have been copied from the large collection in the possession of the publishers, due credit having been awarded in every instance to the original source when it could be satisfactorily ascertained. Messrs. Gemrig and Kolbé, of this city, and Messrs. Tiemann & Co., of New York, have supplied me with numerous engravings illustrative of the latest improvements in surgical instruments, apparatus, and appliances.

In taking a retrospect of the last fifteen years one cannot fail to be struck with the extraordinary strides which surgery has made during this brief but prolific period in the world's history. Much of this progress is unquestionably due to the foundation which Dr. Ephraim McDowell unconsciously laid when, in December, 1809, he performed his first operation for the removal of a diseased ovary. To that operation, in the bold hands of the two Atlees, Clay, Wells, Kimball, Dunlap, Keith, Péan, Schroeder, Koeberlé, Thomas and others,

are directly due the brilliant advances which have been made in abdominal and pelvic surgery during this time. To Professor Lister must be accorded not a little praise for the part he has played in this wonderful work. If only one tithe be true of what his admirers claim for him, enough remains to entitle him to the credit of being one of the world's eminent benefactors. It was he who first taught surgeons the importance and value of thorough cleanliness in their operations and dressings, before his time so little understood and so seldom practised. Specialism, too, is entitled to undying praise. It has penetrated with its methods and instruments of research the innermost recesses of the human body, and has achieved, in a comparatively brief period, triumphs which general surgery could not have achieved in half a century, if, indeed, ever. Operative surgery is rapidly advancing towards its finality of perfection; surgical pathology, under the influence of the cell-doctrine and of the plastic genius of Paget, Virchow, Billroth, and others, has been placed upon a permanent basis; and therapeutic surgery was never in so healthful a condition as it is at the present moment. The world abounds in great surgeons, men accomplished in the science, and skilled in the art of healing, capable of interpreting the secrets of pathological processes, of diagnosticating disease, and of performing with ability and readiness all the great operations, formerly the province of a favored few. The time has gone by when any one practitioner can boast of a monopoly of skill or of reputation in this or in that field of surgery; all have a hand in it, although some are greater and wiser and more competent than others. In the marvellous revolution now in progress, it is gratifying to find that American surgery is fully abreast of the surgery of other nations.

SYSTEM OF SURGERY.

CHAPTER I.

IRRITATION, SYMPATHY, AND IDIOSYNCRASY.

It is very difficult, if not impossible, in the present state of the science, to offer any satisfactory definition of irritation, or to assign to this expression its true pathological and practical import, without an intimate knowledge of sympathy or of those various and mysterious relations, anatomical and functional, which exist among the different organs and tissues of the body, and which thus serve to bind them all up into one harmonious, uniform, and connected system. Irritation and sympathy are not only closely associated together, in all the great operations of the economy, but they so constantly run into each other as to render it impossible always to draw a precise line of distinction between them, or to determine what part they respectively play in the production, propagation, and effect of disease. Much of what has been written upon these topics has necessarily been exceedingly obscure, depending not merely upon the intrinsic difficulties of the subject—great and perplexing as they certainly are—but upon the unphilosophical manner in which they have, for the most part, been discussed by surgeons, whose authority has not only never been disputed, but regarded with a blind devotion as surprising as it has generally been unaccountable. To arrive at any other conclusion from an attentive perusal of their writings, is impossible. Every page, nay, almost every paragraph, bears testimony to the fact that they have constantly confounded together affections of a very different, and even of an opposite nature ; that they have, in numberless instances, violated their own definitions of disease ; and that they have attempted to establish systems of treatment based upon principles of the most erroneous and unfounded character.

What is irritation? Is it an entity or a mere myth, a certain undefinable something, which no one can see, but which every one may recognize by its effects? Perhaps the best definition that can be given is that it is a disordered state of the nerves of the affected part, attended with more or less pain and functional disturbance, but not with inflammation, although it may lead to inflammation, if not timeously arrested : in other words, irritation is a disease the predominant symptom of which is nervous derangement. Viewed in this light, it may be considered as holding the same relation to the nervous system that inflammation bears to the vascular ; the one consists essentially in disordered sensation, the other in disordered circulation ; in the one there is pain, but it is the pain of perverted sensation ; in the other there is pain also, but it is the pain of inflammation, as is evinced by the concomitant vascular injection, discoloration, and tumefaction, which are wanting in the former. The differences between irritation and inflammation have sometimes been defined by stating that the former terminates where the latter begins ; as congestion may be said not to be inflammation, but the prelude to that affection. Both may be merged in the latter disease, and may, consequently, serve to augment and perpetuate it.

Irritation may be of limited extent, as when it is confined to one particular organ, or part of the body, and is then said to be local ; on the other hand, it is sometimes widely diffused, manifesting itself at numerous points, and constituting what is termed general

irritation, of which one of the most familiar illustrations occurs in nervous shock, conse-
quent upon severe injury. It is also divided into direct and indirect; in the former case,
the irritation displays itself at the place of the morbific impression; in the latter, on the
contrary, it occurs at a situation more or less remote, sympathy and reflex action being
the agents of its transmission. An example of direct irritation is afforded in the intole-
rance of light which results from over-fatigue of the eye: and of the indirect, in the con-
vulsions which supervene upon the presence of worms in the alimentary canal, the irrita-
tion being communicated here from the nerves of the bowels to the spinal cord, or the
cerebro-spinal axis, and from thence to the nerves of the voluntary muscles, the seat of
the spasmodic action.

Local irritation may manifest itself in a great variety of ways and circumstances. It
is generally excited by the contact of some extraneous substance, or agent, foreign to the
part, and, therefore, a source of offence to it. Thus a drop of alcohol, falling upon the
eye, instantly produces pain, and injection of the conjunctiva, with an abundant flow of
tears; the organ resents the aggression, and the consequence is a marked perversion both
of sensation and circulation, which, the exciting cause ceasing to operate, soon passes off,
the parts regaining their comfort and accustomed action; or, the cause continuing in play,
violent and even destructive inflammation may succeed, the minor evil being merged into
the major. A pinch of snuff will excite sneezing by the irritation which its presence
induces in the pituitary membrane; on the same principle, some emetics cause vomiting,
some cathartics purging, and some diuretics an increased secretion of urine. When the
hand is held near a hot stove, or rubbed with spirits of ammonia, the skin presently shows
signs of irritation: its sensibility is perverted, it burns and stings, and becomes intensely
red. All these, and numerous analogous cases that might easily be adduced, if it were
necessary, are examples of local irritation, or of perverted nervous action, accompanied
by vascular determination, but not by inflammation, although such an event is certain to
occur, if the exciting cause of the irritation be not promptly removed.

Indirect, or reflex irritation, like the direct, also displays itself in different ways, and
not unfrequently in a manner not less singular than perplexing, defying all effort at expla-
nation. The subject offers a wide field for contemplation and study. Here I can only
glance at a few of the more prominent facts which naturally connect themselves with such
a discussion. To do anything even like partial justice to the subject, it will be proper to
consider it in relation to the principal organs of the body, a procedure which will neces-
sarily bring up the question of sympathy, as a knowledge of the latter is indispensable to
a correct appreciation of the former, and conversely.

It would be out of place in a work of this kind to inquire into the nature of sympathy.
All that we know respecting it is that there exists, both in health and in disease, an inti-
mate relationship between certain organs and tissues, the result either of a continuity of
structure, similarity of tissue, or of ties, of which anatomy and physiology have failed to
point out the true character. In health, this action is carried on so imperceptibly as to
escape attention; but, whenever there is any serious disorder of the system, it manifests
itself at every point, serving at once, at least in many cases, to indicate the nature of the
lesion, and the particular tissues, or set of textures, which it implicates. It is not difficult
to account for the sympathy that exists between parts that are united together by con-
tinuity of structure, as, for instance, the eye and nose, or the bladder and urethra; or by
similarity of structure, as the fibrous membranes, the diseases of which, as gout and rheu-
matism, are sometimes suddenly transferred from one to another: but in other cases—and
these constitute some of the most interesting and important exceptions—no connection of
any kind can be traced, and we are therefore left in doubt in respect to its real character.
It is only, then, by studying these effects, as they exhibit themselves in different parts of
the body, and under different circumstances, that our knowledge of them can be made
practically available.

1. *Nervous System.*—The brain, from its elevated position in the scale of organs, and
its importance to health and life, is subject, in a remarkable degree, to the causes which
develop and influence irritation. Connected, either directly or indirectly, with every
other organ and tissue of the body, its functions are liable to be disturbed in every variety
of way, and in every possible degree, from the most simple and almost imperceptible
departure from the normal standard to the most complete and thorough perversion, amount-
ing, at times, to total annihilation of sensation. Hence, it is not surprising that while the
brain is itself a source of irritation to other parts, it should in its turn, be more or less
seriously affected by irritation having its seat in remote structures operating upon it through

sympathy, or reflex action. It is in this manner that are developed many of the most distressing diseases of the cerebrum and cerebellum, and also, as a natural consequence, of the mind; and what is remarkable is, some of the most disastrous lesions often have their origin in apparently the most trivial cerebral irritation, which, but for neglect or ignorance, might usually be relieved by the most simple treatment. The arachnitis of infancy generally begins in reflex irritation, which has its seat in the bowels, stomach, liver, skin, or gums, fretted, perhaps, by the pressure of an advancing tooth. Such cases are of constant occurrence in this country, during our hot summer months, and there are none which are more justly dreaded by the practitioner. The influence of this kind of irritation is often forcibly exhibited in traumatic delirium, or that excited state of the brain consequent upon accidents and operations, especially in subjects of intemperate habits and of a nervous temperament; the brain appears to be in a state of the utmost tension from pent-up irritability, which nothing but the most liberal use of anodynes can generally control; all the symptoms are such as to preclude the idea of the existence of inflammation in the cerebral substance, nor is it by any means certain that there is always gastritis, although usually there is marked derangement of the stomach. In disorder of the uterus, the brain is often affected by reflex irritation, as is plainly evinced by the eccentric phenomena which so generally attend hysterical diseases.

On the other hand, disease of the brain is often productive of serious irritation, or disease in other parts. Thus, after concussion of this organ, it is by no means uncommon, after the main symptoms of the accident have subsided, to meet with paralysis of one side of the face, occasional vomiting, constipation of the bowels, irritability of the bladder, or disease of the sphincters, causing involuntary discharges of urine and feces.

The sympathies existing between the cerebellum and the testes afford a ready explanation of the occurrence of certain diseases, which, but for a knowledge of this fact, would be inexplicable. Military surgeons long ago noticed that wounds of the occiput, even when not involving the substance of this portion of the brain, are often followed, at variable periods after recovery, by atrophy of the testicles. Injuries of the cerebellum have been known to be succeeded, within a short time after their infliction, by the most violent sexual excitement. A case of gunshot wound, in a man twenty-five years of age, related to me by Dr. Donne, admirably illustrates the nature of such a lesion. The ball, a common rifle one, penetrated the skull near the lambdoidal suture, whence it passed obliquely downwards and backwards, lodging, there was every reason to believe, in the cerebellum. The reaction, which was very slow, was attended with excessive excitement of the genital organs. Intense priapism supervened on the fifth day, attended with the most extraordinary salacity, which formed the all-absorbing topic of the man's remarks during his semilucid intervals up to the time of his death, nine days after the receipt of the injury. Nocturnal pollutions and the habit of onanism, in their most degrading forms, are often excited and kept up by a diseased state of the brain operating prejudicially upon the testes and seminal vesicles. The effect may be produced simply by inflammation of the cerebral tissues, or by the pressure occasioned by some morbid growth, as a sarcomatous, scrofulous, or other tumor.

The study of the sympathies and irritations of the *spinal cord* naturally follows that of the brain. Connected, as this cord is, on the one hand, by the nerves which are detached from its substance, with the organs of volition and of special sensation, and, on the other, by the anastomoses of these same nerves with those of the great trisplanchnic system, its sympathies and relations are as universal as they are close and intricate. Hence whatever has a tendency to derange these consentaneous movements, must necessarily be a source of disease, often of a wide-spread, if not of an all-absorbing character. Concussion, for example, of the spinal cord, when not immediately followed by death, is generally productive of excessive prostration of the vital powers, hardly less extensive and fatal than that of the brain itself. Life often hangs literally for hours upon a mere thread; the face is ghastly pale, the pulse weak and fluttering, the breathing hardly perceptible. In the milder forms, the mind is frequently disordered for days, the bladder is excessively irritable, the bowels are costive, the eye sees objects confusedly, and the ear is incapable of accurately noting sound. There are many diseases which may induce spinal irritation; I shall allude only to inflammation, ulceration, and displacement of the uterus, the practice of self-pollution, constipation of the bowels, and chronic gastric disorder. On the other hand, spinal irritation is capable of sending its baneful influence through every portion of the system, deranging the functions of every organ, and causing a train of phenomena frequently as distressing as they are enigmatical, or difficult of interpretation. Nervous headache, hemicrania, partial paralysis, imperfect sight, partial

aphonia, embarrassed respiration, palpitation of the heart, gastric irritation, vitiated appetite, costiveness, and disorder of the menstrual secretion, are often directly traceable to disease of the spinal cord and its envelops; and no practitioner can make much progress towards a cure in these affections without bearing in mind the sources whence they spring. The renal secretion is often greatly deranged by disease and injury of the spinal cord, and a very common effect of such lesions is a tendency to various deposits, especially the lithic and phosphatic. The bladder is also liable to suffer under such circumstances; becoming irritable, inflamed, and the seat of calculus, especially when the spinal cord has been severely concussed, wounded, or compressed. Many cases of neuralgia, gout, and rheumatism owe their origin, there is reason to believe, to disorder of the spinal cord, or the spinal cord and brain.

The *nerves*, those agents which convey to and from the brain and spinal cord the impressions made upon the various organs of the body, are themselves not unfrequently the seats of serious diseases and injuries, serving to modify and pervert their functions. A spicule of bone, a ball, or the point of a needle, pressing upon a nerve, or partially imbedded in its substance, has often been productive of epilepsy, partial paralysis, loss of sensation, and other unpleasant symptoms, which promptly vanished upon the removal of the foreign body.

2. *Heart.*—As the heart is sympathetically connected with every portion of the body, so there are few diseases which are not capable of exerting a prejudicial influence upon its action, exalting it at one time and depressing it at another. It may be irritated and fretted in a thousand different ways; now by this cause, and now by that; at one time by the solids, and at another by the blood, its natural and proper stimulus. Both the surgeon and physician daily witness examples of these disturbing agencies, and prepare to meet them by the judicious exercise of their clinical knowledge, often sadly tried by the perplexing and dangerous features of the case. There is no organ, the brain hardly excepted, the action of which varies so much as that of the heart within the limits of health, and none which suffers more frequently and profoundly in disease and accident. The blood which, on the one hand, serves to animate and rouse it, and which, on the other, it is obliged at every moment to propel to every portion of the body, is itself one of the greatest sources of irritation to which it is so constantly exposed. At one time the cause of the irritation perhaps is plethora, at another anemia; in one case it may be due to an undue proportion of saline matter, in another to the presence of some extraneous substance. Among the more prolific sources of cardiac irritation are disorder of the digestive apparatus, mechanical obstruction to the circulation, however induced, mental emotion, and derangement of the liver, uterus, and kidneys.

In injuries, derangement of the sympathetic relations of the heart is of constant occurrence, exhibiting itself in various forms and degrees, from the slightest disorder of its functions to almost complete annihilation of its muscular powers. In shock, the pulsations of the heart are weak and fluttering; in compression of the brain, slow and laboring; in hemorrhage, thrilling and vibratory; in plethora, strong and full; in anemia, quick, jerking, and accompanied with a peculiar systolic murmur.

Irritation of the heart is often aroused by compression of the cardiac nerves by various kinds of tumors, by aneurism of the great vessels, and by diseases resident in its own tissues, causing them to act in an irregular and imperfect manner.

As the heart's action may be disordered by various diseased states of the body, so may this organ, in its turn, occasion derangement and irritation in other structures, leading not unfrequently to violent inflammations which no remedial measures, however judiciously applied, can always arrest and subdue. These disordered states form a wide field of study, which it would be out of place to pursue in a work of this kind. The intelligent reader will not fail to appreciate their pathological and practical import.

3. *Lungs.*—The action and reaction which are so incessantly going on between the lungs and the rest of the system cannot fail to strike the most superficial observer. From the importance of their functions, and their extensive sympathetic relations, these organs are subject to numerous and diversified changes, the influence of which, upon the general health, can only be duly estimated by a profound study of the subject. Whatever seriously affects the functions of the more important structures, is sure, sooner or later, to exert an unfavorable impression upon the lungs, disordering the respiratory movements, and untowardly interfering with the aeration of the blood, or the introduction of oxygen, and the elimination of carbonic acid. Hence, a perfectly healthy state of these organs is

a matter of paramount importance in the treatment of every case of injury and disease. Among the more common objects of attention, with this view, should be a pure state of the atmosphere, the use of wholesome food, and the correction and improvement of the secretions, without which our best directed efforts will often fail to avert irritation and disease, or to combat them successfully when their development has been unavoidable.

4. *Digestive Organs.*—The *stomach*, possessing a wide range of sympathy, is often the seat, not less than the cause, of severe irritation. Food and drink are the natural stimulants of this organ, and, rationally employed, seldom prove unwholesome. But when the laws of digestion are contravened by dietetic debauch and indiscretion, or, in other words, when the stomach is overloaded with indigestible articles, nausea and vomiting, with more or less cerebral and other disturbance, are the necessary and inevitable consequences. In children and delicate nervous females, such abuse often manifests its effects in the most violent convulsions, from the irritation it produces in the cerebro-spinal axis and the nerves which are distributed to the voluntary muscles. An over-loaded stomach frequently brings on a severe attack of asthma, palpitation of the heart, indistinctness of vision, and distressing noises in the ears.

Affections of the *œsophagus* often create excessive irritation of the stomach, manifesting itself in nausea and vomiting. Examples of this morbid sympathy occur in carcinoma of the œsophagus, as well as in ulceration and in ordinary stricture of that tube. I have seen a foreign body, as a common cent, lodged in the œsophagus of a child, keep up nausea and vomiting until it was extracted. The irritation of the stomach, produced by tickling the fauces, is well known to every one. On the other hand, the œsophagus is liable to suffer very seriously from disease of other parts of the body. Thus, spasmodic stricture of this tube, sometimes of an exceedingly severe and intractable character, may be produced by disorder of the stomach, bowels, uterus, or spinal cord, which can only be relieved by addressing our remedies to the seat of the primary affection.

Disorder of the *bowels* is a prolific source of irritation, exhibiting itself in different viscera and tissues; for there are few organs whose sympathetic relations are of a more varied and extensive character. Allusion has already been made to the effects occasioned by the presence of worms in the alimentary canal; the retention of irritating matter often produces similar impressions upon the great nervous centres, followed in many cases, especially in infants and delicate nervous persons, by violent convulsions, disease of the arachnoid membrane, and palpitation of the heart. Itching of the nose, and various affections of the lips, tongue, and fauces, are frequently directly chargeable to dyspepsia, constipation, and other gastro-enteric derangement. What is called sick headache affords a familiar illustration of cerebral irritation dependent upon disorder of the stomach and bowels, or of these organs and of the liver. Costiveness never fails, when long continued, to oppress the brain, and to produce a sense of general malaise. Excessive itching of the pudendum and perineum is sometimes caused by the existence of worms in the alimentary canal.

There is an intimate sympathetic connection between the bladder and the rectum; also between the urethra and the lower bowel. In dysentery, hemorrhoids and fissure of the anus, strangury and spasmodic retention of urine are by no means uncommon, and are sometimes productive of great suffering. The ligation of a pile not unfrequently compels the surgeon to use the catheter for drawing off the urine; and I have known the vesical irritation in such a case to continue for several days. The same affections often cause spasmodic stricture of the urethra.

A very lively sympathy exists between the *teeth* and some of the other parts of the body; more intimate and extensive than would at first sight seem possible. Children, from the pressure of the teeth upon the gums, are extremely liable, especially during our hot summer months, to vomiting, diarrhœa, fever, and convulsions. Arachnitis occasionally supervenes upon difficult dentition; and certain affections of the skin, as eczema and porrigo, are frequently directly traceable to its effects, and rendered obstinate, if not temporarily incurable, by its persistence. A heated and tumid state of the gums, with thirst and redness of the skin, should be promptly met by the free division of these structures; otherwise, what is originally a mere irritation of the brain, stomach, or bowels, may soon be transformed into a fatal inflammation.

A decayed tooth, even when it does not itself ache, often causes severe pain in the face, temple, neck, throat, or ear; generally, but not by no means always, on the corresponding side, doubtless because all these parts are supplied by nerves derived from the same sources. When the ear is involved, the pain is propagated along the nervous cord of the tympa-

num, a filament of the second branch of the fifth pair of cerebral nerves. A carious tooth occasionally creates violent pain in a sound one, though at a distance from it, the suffering ceasing the moment the offending tooth is extracted. I have known a severe attack of pleurodynia to be kept up by a diseased tooth; the patient was bled and purged, but relief came only with the removal of the affected stump. Enlargement of the lymphatic glands of the neck, ulcers of the chin and cheek, epilepsy, hysteria, dyspepsia, and various other affections, sometimes of a very obstinate and distressing character, may be produced by carious teeth. It is difficult to conceive how a diseased tooth could keep up an attack of rheumatism of the hip, and yet the possibility of such an occurrence is established by some well-authenticated cases. Dysmenorrhœa has been cured by the extraction of several of the large grinders; and attacks of intermittent fever have been relieved in a similar manner, after the protracted but fruitless employment of bark and other remedies. A decayed tooth has been known to produce neuralgia of the arm, which promptly vanished upon its removal. Amaurosis, temporary and permanent, has occasionally been caused by diseased teeth in the upper jaw. In a case related by Hancock, a boy eleven years old was rapidly cured of total blindness by the extraction of two permanent bicuspids and four milk molars. Fricard met with a case of severe and obstinate tonsillitis, which yielded only after the free division of the indurated and swollen gum over the wisdom tooth.

The sympathetic relations of the *liver* are at once numerous and diversified, and any disturbance in them is generally productive of irritation in a number of the more important organs, especially the stomach, bowels, brain, heart, and lungs. The skin also frequently suffers in consequence of hepatic derangement, and, conversely, the liver from disorder of the cutaneous surface. Various medicines, as well as different kinds of food, are capable of seriously disturbing the functions of this organ; and it is well known that its secretions are often materially disordered by the direct influence of anxiety or strong mental emotion. An attack of jaundice is sometimes instantaneously produced by severe fright. The timid duellist and the affrighted soldier often suffer from this kind of irritation. Hepatic abscesses not unfrequently follow upon injury of the skull or brain; and, on the other hand, disease of the liver occasionally provokes serious cerebral irritation. Dyspnœa, palpitation of the heart, nausea, flatulence, and vomiting, are common effects of disease of this viscus. Pain in the top of the right shoulder has long been recognized by physicians as a symptom of hepatitis. Violent shock is occasionally followed by total suppression of bile; and the passage of a gallstone always causes intense gastric irritation.

5. *Urinary Organs.*—The *kidneys* have important sympathetic relations with different parts of the body, manifesting themselves in various forms of irritation. Thus, a renal calculus excites pain in the urethra, and a desire to urinate, and as it descends along the ureter, it occasions retraction of the testicles, and excessive irritability of the stomach. Severe injuries, involving great shock of the system, are often followed by total suppression of urine; and, on the other hand, there are various affections in which this fluid is poured out in enormous quantity.

The *bladder* also is variously affected by disturbance of its sympathetic relations. After injuries, as compound fractures and severe operations, the organ is often incapable of contracting upon its contents, thus necessitating the employment of the catheter; its perceptive faculties are suspended, and a few days usually elapse before they are reinstated, so as to enable the patient to pass his water without assistance. Stone in the bladder causes pain and burning in the head of the penis, and retraction of the testicle. Sometimes the pain is felt in the knee, heel, and foot; and a curious case has been reported where it was seated in the arm. For a long time the professional attendants were unable to discover the cause of the suffering; but at length, the man complaining of vesical trouble, a sound was introduced, when he was found to have stone, the removal of which put at once a stop to the unpleasant symptom. A very common effect of stone in the bladder is spasm of the sphincter muscle of the anus, which is often so great as to interfere with the passage of the finger. The introduction of a bougie into the urethra occasionally induces swooning, followed by violent rigors and high fever; and cases occur, although they are not common, of severe pain being excited in the extremity of the coccyx by such an operation. In the female, a papillary tumor at the orifice of the urethra will occasionally cause intense pain in the region of the bladder and kidney, with a frequent desire to urinate, and excessive scalding in passing water; in short, a train of phenomena closely resembling that produced by vesical calculus. A tight and elongated prepuce has been known to produce amblyopia and incontinence of urine.

6. *Genital Organs.*—There is perhaps no class of sympathies of greater interest, in a pathological and practical point of view, than those which subsist between the uterus and the general system. It was a knowledge of this circumstance which induced Aristotle to say that the womb was an animal within an animal. The morning sickness of early pregnancy, the hysterical convulsions, the depraved appetite, the rigors which usher in labor, and the contraction of the uterus when the cold hand is suddenly applied to the abdomen, are all examples of the mysterious relations by which this organ is bound to the rest of the body. Nowhere do these effects display themselves more strikingly than between the uterus and the mammary gland. During pregnancy, the breasts begin to sympathize at an early period, as is evinced by their tender and tumid condition ; and the effect which the application of the child to these organs has, soon after delivery, in causing after-pains, is familiar to every one. A knowledge of this fact has induced obstetric practitioners to take advantage of this means as a remedy for inducing contraction of the uterus in case of tardy expulsion of the placenta, or tendency to hemorrhage of this organ. The derangement of the stomach which accompanies prolapse of the uterus, the pain and swelling of the mammary gland from menstrual irritation, and the suppression of the lacteal secretion in puerperal fever, may be cited as additional illustrations of the intimate connection between the womb and the rest of the system. Excessive and intractable pruritus of the pudendum is occasionally produced by congestion of the uterus. Endometritis and congestion, ulceration, and a granular condition of the neck of the womb, especially in young females, occasionally give rise to severe pain in the hip and knee, to great distress in the head, to tenderness of the spine, to palpitation of the heart, to suffocative feelings, and to a host of other anomalous symptoms, generally promptly relieved by the removal of the exciting cause. Stone in the bladder has been known to simulate ulceration and carcinoma of this organ, causing a most embarrassing train of morbid phenomena.

An intimate sympathy exists between the testicle and the parotid gland. In mumps, or inflammation of the latter organ, it is by no means uncommon for the testicle, after the lapse of some days, to take on inflammation also, and generally to such an extent as to bear nearly the whole brunt of the disease. The translation of the morbid action is usually quite sudden, and the suffering of the testicle is often much greater than that of the parotid, being not only attended with severe pain and swelling, but occasionally terminating in complete atrophy of the seminiferous tubes. In what manner, or in accordance with what law of the animal economy, this occurrence takes place, it is impossible to determine, as there is no similarity of texture between these parts, or any direct nervous connection. The parotid is supplied with filaments from the ascending cervical nerves, and with branches from the fifth cranial ; the testicle, with filaments from the spermatic plexus, formed by the sympathetic.

7. *Skin.*—Remarkable sympathies exist between the skin and the mucous membrane of the alimentary canal, as well as between the cutaneous tissues and other parts of the body. Irritations, the result of a disturbance of these relationships, are of frequent occurrence, and serve to explain many morbid phenomena which, but for our knowledge of this circumstance, would be a complete mystery to us. The sympathy between the skin and mucous membrane is particularly close and intimate, arising from their great similarity of structure, it being well known that these tissues are convertible the one into the other, although there is no direct connection between them, except at the various mucous outlets ; here, however, it is inseparable, and this is perhaps one reason, if not the principal, why disease of the one is apt to cause disorder of the other. The fact that various substances taken into the stomach as food and medicine often produce the most singular cutaneous affections, within a short time after their introduction, is of daily occurrence. Every one's experience informs him of certain articles which he cannot use with impunity. There is no doubt that many diseases of the skin, generally of a very simple character, are often greatly aggravated and rendered obstinate, by inattention to the diet and neglect of the bowels and secretions ; and it will be readily conceded that the practitioner who is aware of this possesses a great advantage in the cure of these maladies over one who is ignorant of the circumstance, or wilfully disregards it. It is generally supposed that the skin suffers more frequently from disorder of the mucous membranes than the latter do from derangement of the former ; but this is probably a mistake. It must not be forgotten that there is a marked difference in respect to the relative frequency of the affections of these two classes of structures in different climates, and at different seasons of the year. In tropical regions the prejudicial effects of a disordered state of the skin show themselves

in a great variety of ways in the mucous membranes, especially those of the stomach and bowels, as in different forms of gastric irritation, diarrhœa, and dysentery. Erysipelas, carbuncle, and furuncle are generally supposed, and very correctly, to be essentially connected with disease of the chylopoietic viscera; indeed the more common varieties of these affections usually owe their origin to derangement of the stomach and bowels, and hence the practitioner rarely makes much progress towards a cure if he loses sight of this pathological relation. An unhealthy state of the skin often produces serious disease of the eye, brain, lungs, and liver, which is promptly relieved by attention to the cutaneous surface. Observation has shown that in bad cases of burns and scalds life is not unfrequently destroyed by ulceration of the duodenum, or the upper portion of the bowel, and yet it would puzzle the most profound physiologist to account for such an occurrence by a reference to any of the known laws of health and disease.

8. *Eyes.*—The eyes, like all symmetrical organs, have an important sympathy, not only with each other, but also with many other portions of the body, which displays itself both in health and disease, and not unfrequently becomes a cause of irritation and inflammation. A familiar example of this internuncial action occurs in cataract. When one eye suffers from this disease, the other, at no distant period, is very apt to become affected also. Even in ordinary ophthalmia a similar liability to the extension of the morbid action is exceedingly common. The sound eye either soon takes on inflammation, or, if it be so fortunate as to escape this disease, it is sure to become the seat of such an amount of morbid sensibility as to render it temporarily unfit for useful vision. A percussion cap, or other foreign body, lodged in one eye, has not unfrequently been the cause of destructive inflammation in the other; and this disposition to the involvement of both organs, where one is originally exclusively affected, is nowhere more forcibly and painfully exhibited than in amaurosis. It is true, it is not always easy, under these circumstances, to determine, in any given case, what share of the disease in the eye secondarily affected is due to the influence of consentaneous irritation, or to the operation of the same morbific agency which provoked the original malady; but it may reasonably be assumed, in the absence of positive information, that much, in the majority of instances, is the direct result of deranged sympathy. This liability of the eyes to participate in each other's diseases seems to be due to the intimate connection which exists between the optic nerves; and the same circumstance serves to explain the reason why the eyes are so frequently affected in organic disorders of the brain.

The eyes and nose are intimately related with each other, first, through the disturbance of the ophthalmic branch of the fifth pair of nerves, and, secondly, through the pituitary membrane, which is prolonged upwards through the lachrymal passages to form the conjunctiva. Hence it is easy to see how catarrhal affections should induce pain and redness in this membrane as it is reflected over the eyes; how snuff should excite a flow of tears; and how sudden exposure of the eyes to a strong light should cause sneezing. The connections which the frontal, infraorbital, and other nerves form with the filaments of the ophthalmic ganglion enable us to explain the occurrence of amaurosis in consequence of blows, wounds, and neuralgia of the face, eyebrows, forehead, and temples.

The eyes are connected with the abdominal viscera, particularly the stomach and bowels, through the medium of the branches of the sixth pair with the great sympathetic. The partial blindness consequent upon gastro-enteric irritation is readily accounted for in this way; and the same circumstance serves to explain the dilated state of the pupil which occasionally attends the presence of worms in the alimentary canal of children. It is probable that the pneumogastric nerves also play an important part in these sympathetic relations, otherwise it would be difficult to assign a reason for the excessive nausea and vomiting which now and then supervene upon injuries and operations of the eye, as severe blows and the depression of the cataract.

The eyes and teeth sometimes actively sympathize with each other, caries of the latter occasionally keeping up violent inflammation of the former, which promptly disappears upon the removal of the offending organ. I have several times seen the photophobia attendant upon strumous ophthalmia speedily yield in this way, after the failure of numerous other remedies.

9. *Ears.*—A curious sympathy, noticed by all aural practitioners, exists between the ears and the respiratory apparatus, and also between the ears and the stomach. Thus, pruritus of the auditory tube sometimes provokes coughing and vomiting; and the former of these effects, it is well known, is not unfrequently caused simply by probing or spong-

ing this passage in the removal of wax, or the extraction of a foreign body.   Sir William Wilde, in referring to this phenomenon, says that it is by no means unusual, although it cannot be produced in all cases. " I never witnessed it," he continues, "in children or very young persons; it is most common in males of about middle life, and is in no wise connected with any previous disease existing in the respiratory apparatus.   In some persons the slightest touch of the floor of the external auditory passage, about midway between its external outlet and the inferior attachment of the membrana tympani, will bring on violent irritation and spasmodic action in the larynx.   In this case also the patient will generally tell us, upon inquiry, that he does not experience pain; but the moment we touch this very sensitive spot he feels a tickling sensation in his throat, which immediately increases to the feeling one has when "a bit is gone astray."   What the nervous connection is which induces this has not been fully determined, but the fact is worthy of note."

Arnold has reported a case of chronic vomiting in a child, which long resisted a great variety of remedies, but was promptly cured by the extraction of a bean from each ear, the foreign substances having been introduced during play.   Mr. Toynbee had a patient who suffered under a cough which no treatment could subdue, but which promptly and permanently disappeared upon the removal of a fragment of dead bone from the auditory canal.   Numerous instances have been recorded of vertigo, reeling, and vomiting, caused by diseases of the ear.   Generally, those affections are chronic, and are often erroneously imputed to disorder of the stomach, liver, and bowels.

10. *Age and Effects.*—All persons are liable to suffer from irritation; but there is, as might be supposed, great diversity in this respect, in different individuals.   Thus, it is well known that persons of a nervous, irritable temperament are more prone to it than the sanguine and leucophlegmatic, owing no doubt to the fact that they possess a more delicate nervous system.   Women suffer more frequently than men, both from local and general irritation; and some of the worst forms of reflex irritation that the practitioner meets with occur in hysterical females.   Infants and children are extremely liable to the disease, the slightest cause often serving to light up the most distressing suffering.   Loss of sleep, anxiety, grief, hard study, intemperance, inordinate sexual indulgence, impoverished diet, and the enervating effects of a hot climate, all powerfully predispose to the occurrence of irritation.   The inhalation of impure air is another well-known cause operating injuriously upon the system.   A student who spends his nights in the foul atmosphere of the dissecting-room will be much more likely to suffer severely from the prick of his finger than one who enters it only occasionally.   In the one case the constitution is deteriorated by exposure, and therefore incapable of resisting the effects of disease; in the other it is healthy, and indisposed to take on morbid action.

An irritable state of the system often sadly interferes with the reparative process. Thus, the healing of a wound is sometimes suddenly arrested by an unhealthy state of the system, manifesting itself in a general exaltation of the nervous sensibility, altogether incompatible with the development of healthy blastema.   An aneurism of the aorta, attended with constitutional irritability, has been known to prevent the consolidation of a fracture of the femur.   These, and other similar facts, are of deep practical interest, as they are suggestive of valuable therapeutic measures.

Another very common effect of irritation, especially when extensive or seated in an important organ, is derangement of the secretions, not only of the parts more immediately affected, but of the rest of the system.   Thus, irritation of the brain, however induced, is very certain to disorder the functions of the stomach, liver, and kidneys, as evinced by indigestion, a bilious appearance of the skin, and a high-colored and scanty state of the urine.   The salivary glands, too, suffer, the mouth becoming dry and viscid; the head aches, the pulse is excited, and the extremities are cold.

Idiosyncrasy, a subject closely connected with irritation and sympathy, literally signifies a peculiarity of constitution, or a state of the general system in which certain articles, whether taken as food, drink, or medicine, produce an effect altogether different from what they do under ordinary circumstances.   Thus, lobster and other varieties of shellfish, although they may be used with perfect impunity by most persons, are extremely prone in some individuals to induce urticaria, vomiting, and purging.   A young lady, a patient of mine, married, robust, and of a florid complexion, cannot eat eggs, no matter how prepared, without being almost immediately seized with vomiting.   A gentleman of my acquaintance is always copiously purged after eating soft-boiled eggs; hard-

boiled eggs always agree with him. Milk acts on him in a manner similar to that of soft-boiled eggs. One of my grandchildren cannot eat strawberries without being instantly seized with some pain in the stomach. Some persons are overpowered by a particular odor or by the sight of blood. I know a lady who has not been able, for many years, to eat watermelon without being very speedily attacked with hoarseness, and soreness of the throat and mouth, attended with a burning, pricking sensation, nausea, and colicky pains. The use of watermelon-seed tea invariably produces a similar effect. Another lady, formerly a patient of mine, can never take an ordinary dose of laudanum without being copiously purged; opium affects her in a similar manner, but morphia does not. Laudanum, administered by the rectum, vomits freely and nauseates for many hours. These articles, however, always afford relief to her suffering. A lady patient of mine always experiences severe gastric pain after taking a dose of morphia or laudanum, or, in fact, opium in any form. In several persons of my acquaintance, among others a physician, the inhalation or odor of ipecacuanha invariably excites a violent attack of asthma, generally lasting for two or three days. In the case of the medical practitioner, the perception of the presence of this substance is so keen that, if he be in the third story of a house on the first floor of which an ordinary dose of the article is compounded, he is instantly seized with spasmodic cough and wheezing. A gentleman, for many years my patient, cannot drink a cup of green tea without being promptly and copiously purged; it usually operates on the bowels in from fifteen to twenty minutes after it is taken, bringing away thin, watery evacuations, accompanied with more or less griping; black tea produces no such effect, which he has experienced from the green from his earliest recollection. In two other cases, the use of green tea, even in very small quantity, invariably acts as a powerful diuretic, causing an abundant secretion of urine, with a frequent desire to void it for a number of hours. I lately prescribed for a middle-aged man, who is always copiously purged when he takes a glass of milk-punch, the action generally commencing in about one hour from the time he swallows it. Dr. Prout knew a man who could not eat mutton; no matter how it was disguised, he always promptly detected it, and it invariably caused violent vomiting and purging.

A patient of mine, an habitual asthmatic, thirty-five years of age, a tradesman by occupation, cannot enter a room where feathers are, without instantly experiencing an aggravation of his pulmonary affection. To provoke this effect, it is not necessary that he should see or smell the feathers; led blindfold into an apartment thus furnished, he is at once conscious of their presence, and is immediately compelled to retreat.

Idiosyncrasy not unfrequently displays itself in the operation of various medicines, affording thus useful hints to the practitioner in the selection of his remedies. There are many persons who cannot take opium in any form without being kept awake by it for hours and even days, besides suffering greatly from nausea, excessive itching, delirium and other distressing symptoms. The most minute quantity of mercury will, in some persons, cause profuse ptyalism, while in others the article may be given in large doses and for a long time without the slightest effect of this kind, the system being absolutely proof against the action of the medicine in any of its forms and modes of exhibition. Most individuals are freely purged by a drop of croton oil, and yet an instance is occasionally met with, in which hardly any operation upon the bowels is produced by twenty times that quantity.

The above instances, which might be multiplied to an almost indefinite extent from my own experience, will serve to illustrate a class of the most singular affections, the influence of which in modifying, if not in inducing disease, is eminently worthy of the attention of the practitioner.

TREATMENT.—In the treatment of irritation there are several leading indications which claim special attention. The first is to remove the exciting cause; the second, to correct the secretions; and the third, to palliate the disease, both primary and consecutive.

To remove the exciting cause of irritation is not always an easy task. In many cases, indeed, it is either wholly inappreciable, or can only be conjectured. The duty of the surgeon of course plainly is to get rid of it if he can; the ball, the calculus, the splinter of wood, the dead piece of bone, and the carious tooth, are promptly extracted. Irritating ingesta are dislodged by emetics; offending feces by purgatives; worms by anthelmintics. The mortified toe is amputated; the compressed gum lanced; the suppurating felon freely laid open. Light is excluded from the inflamed eye; noise from the suffering ear; cold from the shivering surface. In all such cases the indication is evident, and in general easily fulfilled. But it is otherwise when the cause is occult. Here the disease must be

met on general principles; and the judicious practitioner will do well to look into the condition of his patient's secretions, his bowels, and his diet, which are among the most common sources of the disease.

The correction of the secretions is a matter of primary importance in every case of irritation, whether local or constitutional. The manner of doing this will necessarily depend upon the character of the suffering organ; but no practitioner will fully discharge his duty, if he neglect attention to this point. The viscera whose derangements are most liable to provoke reflex irritation, are the stomach, bowels, liver, and uterus, and they should, therefore, always be objects of special consideration. Not unfrequently the cause of the trouble will be found to exist in irritation of the spine, or of some particular portion of the brain, demanding local depletion and counter-irritation, with perfect tranquillity of mind and body. Whatever the cause of the disturbance may be, it will be found that purgatives can rarely be dispensed with, while in not a few cases they constitute the chief anchor of our hopes. The diet, as a general rule, should be mild and unirritant, the proportions of its nutritive principles varying with the exigencies of each particular case.

The last indication is to cure the disease, or to palliate it if it be irremediable. To point out the methods of doing this in a class of affections of so protean a character as this, would be absurd. Every case must necessarily suggest its own treatment. In ordinary instances antiphlogistics, properly so called, may usually be dispensed with, and large draughts made upon the narcotic class of remedial agents, as their direct influence is to allay pain and spasm, and induce tranquillity of the system. The choice of the particular articles must be regulated by the circumstances of the case, and will often require no little judgment and experience for its successful exercise.

CHAPTER II.

CONGESTION.

It is practically a matter of no little importance that the surgeon should be able to discriminate accurately between inflammation and congestion; or, in other and more comprehensive terms, that he should possess clear and definite ideas respecting the more essential differences between these two morbid states; for upon their correct appreciation must often depend the result of his treatment. The subject, it must be confessed, is one of no ordinary difficulty, and a careful examination of what has been written upon it will serve to convince any unprejudiced mind that there are no two points in pathology concerning which there still prevails a greater amount of confusion; for what one author considers as congestion, another with equal confidence calls inflammation, and conversely; leaving thus the young and inexperienced practitioner in painful doubt not only in respect to the nature of the disease, but, what is far worse, in regard to its proper management. As the subject of inflammation will be fully discussed in the ensuing chapter, I shall limit myself here to a plain and simple exposition of some of the more important facts relative to congestion, preceded by an attempt to assign to this expression its legitimate import.

Congestion signifies an accumulation of blood in a part, the result either of some mechanical obstruction, or of disordered innervation, interfering with the onward movement of the sanguineous fluid. The word is synonymous with hyperemia, which Andral has proposed, without any just reason, as a substitute for it. It simply denotes the existence of an abnormal quantity of blood in a part, without any of the ordinary phenomena and effects of inflammation, which, however, it generally accompanies, if indeed it does not form a necessary consequence of the increased quantity of blood sent into the suffering structures in that disease. Pathologists usually divide congestion into two varieties, denominated, respectively, the active and the passive. The first, as the name implies, is characterized by inordinate activity of the part, as is evinced by its scarlet complexion, its augmented temperature, and its functional disturbance; and soon leads, if allowed to progress, to various kinds of deposits, particularly the serous and plastic. Passive congestion, on the other hand, is distinguished by the dark color of the part, the enlarged

and sluggish condition of the vessels, and the chronic march of the disease. Owing to these differences in the action and aspect of the affected structures, these two varieties of congestion are often denominated arterial and venous; terms which are ill chosen, as they have a tendency to create erroneous impressions respecting the true nature of the two lesions, for it is impossible to conceive of any case of congestion, however slight or severe, in which the disease is exclusively confined to one set of vessels.

It will thus be perceived that active congestion is closely allied to inflammation, although it does not, properly speaking, constitute inflammation, except in the opinion of certain pathologists, who, it seems to me, are not very felicitous in their attempts at separating the two affections from each other, although it is evident that they strive very hard to do so. They treat of congestion as a distinct entity, and yet they do not hesitate to ascribe to it phenomena and effects which belong exclusively to inflammation, and which congestion, considered in the proper sense of that term, is utterly incapable of producing. Whenever a part, however situated in relation to the amount of blood it contains, is the seat of morbid deposits, it has passed the stage of congestion, and gone over into that of inflammation. If this be not so, then it necessarily follows that active congestion and inflammation are essentially one and the same disease, and that, consequently, it would be absurd to attempt to describe them separately.

In all acute inflammations, whatever their cause or situation, active congestion is a necessary antecedent of the morbid action; one of the first links in the chain of the malady. Hence it would not be improper to say that it is a part of the inflammatory process, ushering in the disease, and continuing up to the very point of effusion; or, in other words, ceasing only where effusion commences. But this is strictly true only to a certain extent; for there is in every case of inflammation a circle beyond the process of the morbid action, where the blood, playing about in eddies, has accumulated in large quantity, distending the bloodvessels, and destined soon to part with some of its constituents, if the disease be merged in the inflammation. A veritable fire is lighted up here; the part is hot, abnormally red, and perhaps somewhat painful; nay, it may be, even a little tumid, from the dilated state of the vessels; the blood moves with unwonted force and velocity; the functional disturbance augments more and more; and presently congestion ceasing, inflammation takes its place, and goes through its allotted course. Another sign of distinction is that, in active congestion, the bloodvessels, although greatly crowded with blood, are more easily emptied than in inflammation: during life by pressure, and after death by injecting matter.

But active congestion is not always necessarily followed by inflammation, although prone to pass into that state if it continue even for a short time. The cause which induced it having been removed, the vessels cease to attract blood in undue quantity, and ridding themselves of what is redundant, speedily regain their normal caliber and function. A familiar illustration of this occurrence is afforded by the conjunctiva, when, from any transient cause, a sudden and violent rush of blood takes place to the affected part; in an instant hundreds of vessels, previously invisible, become apparent, being crowded with red blood, so as to give the surface almost a scarlet hue. Now, if we analyze these phenomena, it will be found that they depend simply upon a dilated state of the vessels of the eye and the presence of an unusual quantity of blood, containing a large number of red globules, which, in the healthy state, are either withheld from these vessels, or which are propelled along them in such small numbers as not to permit their coloring matter to become visible through their delicate walls.

Another familiar example of active congestion is furnished by what occurs in the hand when plunged into cold water, or exposed to a very low temperature. The skin soon becomes remarkably red from an unnatural afflux of blood, the parts are the seat of an unpleasant tingling sensation, and the vessels are exceedingly dilated; still, there is no inflammation, or any tendency to morbid deposit; the suffering structures are only irritated and preternaturally injected. Cautiously treated, the hand soon regains its natural condition, the skin recovers its former hue and sensibility, the blood ceases to accumulate, and the vessels resume their normal caliber. But it is otherwise when the case is unskilfully managed; the congestion then not only continues, but steadily increases, and is soon merged in inflammation, or perverted action and effusion.

Now, what occurs in the external parts of the body, immediately under the eye of the observer, may be supposed to happen, under similar circumstances, in the internal viscera. Thus, we know that when there is a sudden repulsion of the cutaneous perspiration, the blood is extremely apt to collect in the lungs, causing active congestion of the pulmonary tissues, so often the precursor of pneumonia. Poison introduced into the stomach almost

instantly induces active congestion of the mucous membrane of that organ, frequently followed, in a few hours, by the most intense and destructive inflammation. A ligature bound tightly round a limb affords a good illustration of the manner in which active congestion may be supposed to be induced in strangulation of the bowel in hernia and in intussusception.

A distinction should be made between active congestion in a part, and a determination of blood to a part. The former is always the effect of some morbific influence; the latter, on the contrary, may be the result simply of a natural cause. Thus, when the infant is applied to the breast, there is an instantaneous determination of blood to the organ, so as to enable the vessels to furnish the necessary supply of milk; during menstruation, there is a marked afflux of blood to the uterus, probably accompanied by more or less active congestion. In blushing, there is a rush of blood to the cheek; in erection, to the penis; in anger, joy, and other emotions, to the brain. Excessive, sudden, and overwhelming determination of blood to the internal organs sometimes takes place during the cold stage of intermittent fever, especially in that variety of it to which Alibert and others have applied the term malignant. In the congestive fever, as it is termed, of the Southern States, death not unfrequently results within a few hours after the commencement of the attack, the system never reacting from the effects of the chill. Scarlet fever occasionally proves fatal in a similar manner; the surface is pale or slightly livid, the extremities are deadly cold, and the internal organs are literally inundated with blood, determination and congestion coexisting in their worst forms.

In passive congestion, the morbid action is distinguished by its peculiarly sluggish character; the vessels are not only dilated, but frequently varicose, tortuous, elongated, and incapable of contracting upon their crowding contents; the discoloration is dark, venous, or purple, the circulation is tardy and languid, and there is often marked evidence of morbid deposits, especially of serum and lymph, in the cells of the areolar tissue.

Various causes may give rise to passive congestion. The most common are the following; 1st, inflammation; 2dly, mechanical obstruction; 3dly, debility; and 4thly, dependent position.

1st. Inflammation, in whatever form occurring, is almost always followed by a certain degree of passive congestion; the affected parts, exhausted by severe suffering, are reduced in strength and life-power; the vessels, dilated to their utmost capacity, and perhaps partially ruptured, are too feeble to contract upon their contents; the crippled structures are unusually vascular; and the slightest cause is generally sufficient to rekindle the disease. Indeed, as will be stated by and by, an organ that has been once severely inflamed is ever after extremely liable to become inflamed again; passive congestion often lasting for months and even years.

2dly. Mechanical obstruction is a prolific source of passive congestion. Examples occur almost without number, both in medical and surgical practice. I shall allude only to a few, as they will be sufficient for my purpose.

A good illustration of the effects of mechanical obstruction in producing passive congestion is seen in organic disease of the valves of the aorta, impeding the passage of the blood through the lungs. Compelled to remain here habitually in undue quantity, the pulmonary vessels soon fall into a state of passive congestion, which thus acts as a predisposing cause not only of inflammation, to which individuals so affected are extremely prone, but also of pulmonary apoplexy. Obstruction of the larger veins, as the femoral and iliac, is always followed by passive congestion in the parts below. In varicose enlargement of the veins of the leg, attended with disease of their valves, the blood has great difficulty in finding its way to the heart, and the consequence is that the distal portion of the limb is always in a state of passive congestion, with a strong tendency to inflammation, and to different deposits, more especially the serous and plastic. Obstruction of the artery of the leg, by fibrinous concretions, is always followed by congestion and inflammation, if not by gangrene of the foot.

The structures in the neighborhood of morbid growths are generally habitually congested; hence the profuse hemorrhage which so often attends their extirpation. Their vessels being compressed by the overlapping tumor, the passage of their contents is seriously interfered with, and hence they frequently undergo a remarkable dilatation, almost amounting to a real varicosity.

3dly. Debility of a part, however induced, is a frequent source of passive congestion. Examples of this form of the affection are seen in the retina and choroid coat of the eye from over-exertion of that organ, and in various parts of the body from loss of innervation, profuse hemorrhage, or other discharges, and from the natural wear and tear of the frame. If, under these circumstances, any particular organ is more feeble or exhausted

than the rest, it can scarcely fail to become the seat of passive congestion, or congestion and inflammation.

4thly. Dependent position readily gives rise to passive congestion. It is in this way that inflammation of the lungs is so often induced during the progress of lingering diseases and accidents, as typhoid fever, erysipelas, and compound fractures; the disease usually beginning in the posterior portions of these organs, in passive congestion, and proceeding gradually but steadily from bad to worse, until it proves fatal, a result so much the more to be dreaded on account of its insidious character. In the so-called bedsores, consequent upon long confinement in one posture, during which the pressure of the body is concentrated with peculiar force upon the sacrum, the iliac crest, and the great trochanter, similar effects are produced. There is, both in these and similar instances, in the first place a determination of blood to the most dependent portions of the body, then passive congestion, and finally, as a natural consequence, inflammation; often followed, in the latter case, by mortification.

Passive congestion, however induced, is a frequent cause of inflammation; often of a very destructive character, the more so, because the symptoms which attend it are so indistinct, if not so completely disguised, as to prevent the early recognition of their real import. It is for these reasons that the practitioner should constantly be on the alert whenever he has anything to do with diseases and injuries involving long confinement to one particular posture, and an unusual amount of expenditure of the vital forces.

Inasmuch as congestion may be induced by such a variety of causes, it would be folly to attempt to lay down anything like a regular systematic plan of treatment; to do so, would be to encroach upon every department of pathology and practice, both medical and surgical, of which we have any knowledge. The judicious surgeon, knowing how likely the continuance of such a condition is to be followed by inflammation, or to aggravate inflammation when these two states coexist, will do all in his power to avert the evil, or to combat it when he finds it has already taken place. The leading indication of cure, in every case of congestion, is to equalize the circulation; but to fulfil this often demands great judgment and an amount of pathological and therapeutic knowledge such as comparatively few practitioners possess.

CHAPTER III.

INFLAMMATION.

SECT. I.—GENERAL CONSIDERATIONS.

A THOROUGH knowledge of inflammation is indispensable to every practitioner of surgery. It should form the principal subject of his studies during his pupilage, and the main object of his professional contemplation in after-life. When it is recollected that there is hardly any disease which comes within the province of this department of science that does not originate in inflammation, or that is not more or less affected by it during its progress, the truth and force of these remarks will be sufficiently obvious. The smallest pimple upon the nose is, in point of fact, as much an inflammation as an erysipelas that covers the face and head. An ulcer of one of the mucous follicles of the mouth does not differ, in principle, from an ulcer of one of the glands of Peyer, which are the seat of so much disease and danger in typhoid fever. Many of the maladies, vaguely called nervous, are nothing but forms of inflammation, the nature and seat of which it is often difficult, if not impossible, to determine. Their predominant symptoms are of a nervous character, and hence the diseases which they accompany are usually considered as nervous, while in reality the reverse is too frequently the case.

All accidents, of whatever nature or degree, are, if not immediately fatal, necessarily followed by inflammation. The little wound made in cupping, and the bite inflicted in leeching, would never heal without the aid of this process; the parts would remain open, and be the seat of incessant bleeding, or they would become festering and putrid sores. In a word, there would be no repair after any injury, however simple; and operative surgery, instead of being a blessing, would be a positive evil. Thus, it will be perceived, that inflammation is capable of playing, as it were, a double game in the animal economy,

being at one time a cause of death, and at another a source of life. It is for this reason that it is often designated by the terms healthy and unhealthy, according as the one or the other of these states predominates.

Inflammation may be defined to be a perverted action of the capillary vessels and of the perivascular tissues, attended with discoloration, pain, heat, swelling, and disordered function, with a tendency to effusion, deposits, or new products. In addition to these changes, there is also an altered condition of the blood and nervous fluid as an important element of the morbid process. In what inflammation essentially consists, it is as impossible to determine as it is to explain the intimate character of attraction, repulsion, gravitation, or cohesion. Hence, the medical philosopher, in studying its history, is necessarily obliged to limit himself to an examination of its causes, symptoms, and effects, or, in other words, to a rigid analysis of its appreciable phenomena and consequences.

1. CAUSES OF INFLAMMATION.

The causes of inflammation are almost as numerous as the circumstances which surround us, and are either predisposing or exciting. Whatever has a tendency to affect injuriously the mental or physical organization, whether directly or indirectly, is capable either of inducing disease, or of laying its foundation. The predisposing causes are those which produce in the system, or in some particular part of it, certain changes, states, or conditions favorable to the development of inflammation, without actually provoking it. They are usually tardy in their operation, and are either natural or acquired, according as they are inherent in the constitution or dependent upon accidental circumstances. The exciting causes, on the contrary, are those that are directly concerned in awakening the disease, or fanning it, as it were, into existence. It is not always, however, in our power to ascertain either the predisposing or exciting causes of the morbid action, and hence such cases, which are by no means uncommon, are usually known as occult cases.

The natural *predisposing causes* of disease have reference to peculiarities of constitution, and to a tainted state of the economy, in consequence of hereditary transmission. To the former class belong plethora, debility, and nervous susceptibility, which prepare the system for disease, by the changes which they induce in the fluids and solids. Persons who have naturally an undue quantity of blood, as indicated by their ruddy complexion, and the extraordinary functional activity of their organs, are peculiarly prone to inflammation ; their bodies may be compared to a mass of tinder, which the slightest spark is capable of kindling into a devouring flame. Those, on the other hand, who are naturally feeble, are remarkably prone to local congestions, which, especially when they become habitual, are sure to lead to inflammation, often of a very unmanageable character, because it cannot be met by the ordinary remedies. Persons of a nervous temperament are predisposed to maladies of the brain, spinal cord, and sympathetic nerves, as exhibited in derangement of the respiratory, digestive, and genito-urinary apparatus ; maladies which are generally tardy in their progress, and often so obscurely marked as to be difficult of recognition.

The fact that some diseases are transmissible from the parent to the offspring is well known. There are family diseases, as there are family likenesses, manners, and peculiarities ; and, what is remarkable, they are more liable to be communicated by the mother than the father, as if it were her special prerogative to impress her vices, as well as her virtues, upon her descendants. Another law is that some of these diseases may skip one generation to reappear in another, and that it is not necessary that the parents should be actually laboring under an attack of them at the period of conception. The affections which may be transmitted in this way are gout and rheumatism, phthisis, asthma, scrofula, carcinoma, and constitutional syphilis, together with some others which it is unnecessary here to specify. It is in this wise, apparently, that God visits the sins of the parents to the third and fourth generations of their offspring. In what element of the economy the germ of the morbid action is locked up, neither reason nor experience has been able to determine ; for a time it would seem to be latent in the blood, when it explodes, either suddenly, or gradually, with zymotic violence.

Among the acquired predisposing causes of inflammation are, the effects of previous disease, plethora, and debility, however induced. An organ that has once labored under inflammation is extremely prone to suffer from it again from the most trivial causes. The part, enfeebled by the attack, does not recover completely from its effects for a long time,

if ever. Hence, influences which, in the natural state, would not disturb its physiological relations, are, under such circumstances, peculiarly prone to excite disease. A familiar illustration of this fact is afforded in the tonsillitis of children, in whom a recurrence of the malady is generally awakened by the slightest exposure to cold. Organic disease of one organ predisposes to organic disease in another, especially if in intimate sympathy with it. Albuminuria is a powerful predisposing cause of erysipelas, pyemia, furuncle, and carbuncle. It is not necessary here to enlarge upon plethora and debility as predisposing causes of inflammation. If these states of the system are capable of preparing it for the development of disease when they are a natural result of the organization, it may readily be supposed that they would be much more likely to produce such an effect when they are acquired, in consequence of the mode of life of the individual, or of the influence of structural lesion.

Age, sex, temperament, occupation, food, dress, exercise, climate, and season, are all so many predisposing causes of inflammation. Infancy is particularly obnoxious to enteritis, croup, diphtheria, and arachnitis; childhood, to affections of the skin, struma, parotitis, and tonsillitis; manhood, to pneumonitis, carditis, and diseases of the genito-urinary organs; and the decline of life, to gout and rheumatism, asthma, arteritis, and the various forms of malignant maladies.

The differences in regard to the susceptibility to inflammation in the two sexes arise mainly from their anatomical peculiarities, and are much less common than is generally imagined. The function of parturition renders the female particularly liable to peritonitis, phlebitis, arachnitis, and carcinoma; while the male, from his occupation and mode of life, is more prone to cystitis, urethritis, gout, rheumatism, arteritis, hepatitis, pneumonitis, and pleuritis.

Of the influence of temperament, as a predisposing cause of disease, too little is known to enable us to speak with any degree of certainty. The sanguine temperament, characterized by plethora with inordinate capillary activity, disposes to inflammation of the internal organs; the nervous, to inflammation of the nervous system; the lymphatic, to inflammation of the skin, joints, serous membranes, stomach, bowels, and lymphatic glands.

Occupation is a powerful predisposing cause of inflammation. Persons who work a great deal in the open air, and who are much exposed to cold and wet, are extremely liable to suffer from pneumonia, arthritis, tonsillitis, and enteritis. A sedentary life leads to chronic disorder of the alimentary canal; and, if conjoined with constant mental exertion, is liable to be followed by disease of the brain and arachnoid membrane. Excessive exercise of an organ, as of the larynx in singing and speaking, is a predisposing cause of inflammation.

The influence of food in disposing to inflammation is well known. The habitual use of stimulating articles of diet, especially when conjoined with want of exercise in the open air, is among the most powerful of the causes under notice. On the other hand, an impoverished diet, or a privation of nitrogenous food, by inducing a defective blood, leads to scurvy, chlorosis, typhoid fever, scrofula, and inflammation of the serous structures, terminating in dropsical effusions. Certain articles, as ergot, if employed for any length of time, or in any considerable quantity, dispose to arteritis and gangrene of the extremities. The habitual indulgence in alcoholic drinks leads to gastro-enteritis, hepatitis, and attacks of epidemic diseases, whenever such diseases are prevalent.

Dress may be an indirect cause of inflammation. It may keep the body too warm or too cold, or exert injurious compression; in either event, local congestion will be apt to be induced, which the slightest circumstances may fan into disease.

A change of climate, whether from hot to cold, or cold to hot, powerfully predisposes to inflammation. Hence the period of acclimation is always peculiarly trying, and few persons escape without suffering. Season, too, exerts a predisposing influence. Thus, in summer, inflammation is most prone to assail the stomach and bowels; in winter, the larynx, lungs, pleura, joints, and throat.

Mental excitement is a prolific source of inflammation. Fear, grief, anxiety, hard study, and loss of sleep, by deranging the secretions, and interfering with the digestive process, all dispose to this disease. In short, whatever interrupts, disorders, or arrests healthy action, exerts a pernicious influence. This is often the only way in which we can account for the occurrence of erysipelas, carbuncle, rheumatism, cerebritis, scrofula, and carcinoma.

The *exciting causes* of inflammation are extremely numerous, and of the most diversified nature; they act in two ways, either directly upon a part, or indirectly through the sys-

tem. Hence they are said to be local and constitutional ; and the former are either of a chemical or mechanical character.

Among the chemical causes are, first, high degree of heat, as hot water and iron ; secondly, partial application of cold ; thirdly, caustic substances, as the alkalies and acids ; fourthly, acrid vapors, hartshorn, and gases ; fifthly, certain secretions, as urine and bile ; sixthly, blisters, embrocations, and rubefacients ; and lastly, various septic agents, as those of smallpox, syphilis, glanders, and malignant pustule. All these agents act directly upon the parts to which they are applied, either destroying them by their immediate effects, or combining with them in such a manner as to change completely their structure and function. Their operation is always rapid, and the resulting inflammation is usually marked by severe symptoms, both local and constitutional.

The mechanical causes comprise, first, punctures, incisions, contusions, and lacerations ; secondly, fractures and dislocations ; thirdly, sudden and forcible distensions, as from the accumulation of pus, serum, blood, or gas ; fourthly, compression, as by bandage, ligature, posture, or effused fluids ; and fifthly, the presence of foreign bodies, as a stone in the bladder, a bean in the air-passages, a bullet in the flesh, a tubercle in the lung, or a fibrinous concretion in the brain. Thrombosis, or the formation of clots in the blood-vessels, leading to obstruction in the circulation, frequently occasions inflammation. The manner in which these various causes act in producing disease is too evident to require explanation.

The constitutional causes of inflammation make their impression either directly upon the part, or indirectly through some remote structure. Logically speaking, it would perhaps be more proper to say that they all act in the latter way, and not in any case immediately upon the part, as it is usually asserted they do. Thus, a morbific impression primarily made upon the respiratory passages, as the inhalation of some noxious gas, or the contact of malaria, instead of causing disease in the lungs, or in some of its constituents, often, if not generally, explodes upon some other organ, perhaps very distantly, if at all associated with the lungs by sympathy, or similarity of structure and function. A septic poison, as, for example, the virus of smallpox, introduced into the system, acts not merely upon the blood into which it has been conveyed by the absorbent vessels, but also, and mainly, upon the cutaneous tissues, for which it evidently has a greater elective affinity than for any other part of the economy ; if it produces any action at all upon other structures, it is altogether of an indirect character. In the transmission of secondary syphilis from the parent to the offspring, the force of the disease is spent, in the first instance, upon the skin and the mucous membrane of the throat and mouth ; there is no inflammation, so far as we are able to determine, in the connective, fibrous, and serous tissues, or in the internal organs, properly so called. In tertiary syphilis the bones, periosteum, and cartilages are particularly prone to suffer, although the disorder has a more general tendency, as there is more profound contamination of the system.

Whatever doubt, however, there may still be respecting the mode of action of the above agents, there can be none about the operation of heat and cold, which are such prolific causes of inflammation. The influence of a tropical sun, acting upon an impressible nervous system, in producing hepatitis, is well known to the practitioners of our Southern States, and to those of Africa, Asia, and the West Indies. Gastritis and enteritis, in their worst forms, are often developed in a similar manner. The occurrence of tonsillitis, croup, pleurisy, pneumonia, enteritis, cystitis, and rheumatism, as an effect of cold feet, is familiar to every one. In all these instances the primary impression is made through the medium of the skin, by suppressing the perspiration, and throwing the onus of the functional disorder upon some internal and remote organ, between which and the cutaneous surface there is not the least direct connection.

Excessive shock, whether induced by direct nervous exhaustion, or by loss of blood, is a prolific cause of inflammation, often followed by the worst consequences. The inflammation which succeeds to gunshot, railway, and other severe injuries, is generally extremely violent, and is prone, if the patient survive their more immediate effects, to give rise to secondary lesions, often more fatal than the primary. The system thus affected does not seem to have sufficient vitality to keep the morbid action within proper limits : hence its disposition to spread not only over the parts originally implicated, but to other structures, more or less remotely situated.

A part, deprived of nervous fluid, readily falls into inflammation, as is shown in injuries of the forearm involving the division of the radial and ulnar nerves, in which the thumb and fingers, and sometimes even the entire hand, always suffer more or less severely from this cause. Steady and long-continued compression of a nerve, interfering with the

transmission of nerve fluid, may lead to similar results, as is witnessed, for example, in bedsores.

Inadequate supply of food is a common cause of inflammation. Animals starved for experimental purposes are liable to suffer from inflammation and ulceration of the mucous membrane of the intestines; and similar effects have often been observed in persons in health deprived of their accustomed supply of aliment. Scurvy and other affections are produced by a deficiency of alkaline and neutral salts in the blood, especially the salts of potassium. Hence the value of the liberal use of lemon-juice in protracted voyages in the Arctic regions.

The blood itself is a frequent source of inflammation; sometimes, because it is overloaded with earthy salts or other irritating materials, as the poison of erysipelas, carbuncle, pyæmia, and various eruptive diseases; at other times, because of its impoverished condition, rendering it unfit as a supporter of life. There is reason to believe that the latter cause lies at the foundation of many of those low and unhealthy forms of inflammation which so often eventuate in destructive ulceration of the mucous and cutaneous tissues, as well as of some of the worst forms of morbid deposits, as imperfectly vitalized lymph, albumen, and tubercle. Deficient secretion, especially of the liver, kidneys, and skin, is a frequent cause of disease, various substances being thus retained in the circulation, much to the detriment of the general economy, as well as of particular organs, perhaps already predisposed to morbid action. The non-elimination of the products of tissue-metamorphoses is a prolific source of congestion and inflammation.

From the foregoing considerations it will be perceived that inflammation may be *traumatic* or *idiopathic*, that is, produced by external injury or by constitutional causes, the latter of which are often wholly inappreciable by our senses.

Inflammation is sometimes caused by *sympathy*. Thus, the eye occasionally suffers from disorder of the stomach, the brain from derangement of the intestines, the mamma from disease of the uterus, the testicle from lesion of the urethra. A person who habitually overtaxes his digestive powers, and takes withal hardly any exercise, will be very liable, eventually, to perish from carbuncle or erysipelas; or, at all events, to have disease, in some form or other, of the skin, simply because these parts are intimately related to each other by similarity of structure and function. For the same reason disease of the skin is very prone to be followed by disorder of the alimentary canal.

Finally, inflammation may be caused by *metastasis*, an event, which, as the term implies, is characterized by a transfer, for the most part gradual, but occasionally very sudden, of irritation from the part originally affected to another, perhaps at a considerable distance from it, and in no wise related to it by structure or function. In inflammation of the parotid gland the testis is often involved in this way, but why it is, neither our anatomical nor physiological knowledge enables us to explain, as there is no traceable connection whatever between them. In rheumatism of the joints the heart often suffers; and in erysipelas of the skin the morbid action frequently leaves one part of the surface and breaks out upon another. Such occurrences, which are sometimes greatly promoted by our local applications, should always be sedulously watched, as they are generally fraught with danger, especially when they show themselves in important internal structures.

2. EXTENSION OF INFLAMMATION.

All inflammations, of whatever character or grade, are, in the first instance, strictly local, beginning in some particular tissue, spot, or point, from which, as from a common focus, the morbid action radiates in different directions, until it becomes, so to speak, general. Thus, to illustrate, let it be supposed that the malady commences at a certain part of the mucous coat of the small bowel, as, for example, in one of the glands of Peyer. After having remained here for a short time, it gradually spreads to the fibro-cellular lamella, then to the muscular fibres, and finally to the peritoneal investment, involving thereby the whole in one mass of disease. In erysipelas the same law is observed. Here the morbid action, beginning at a little point of skin, gradually extends to the deeper structures, until, as in the case of a limb, it invades connective tissue, aponeurosis, muscle, vessels, nerves, periosteum, and occasionally even bone. A pneumonia, in its progress, usually involves the pulmonary pleura and the bronchial mucous membrane.

The rapidity with which inflammation extends from one texture to another is extremely variable; in some instances the time is very short, perhaps not exceeding a few hours or even a few minutes, as, for instance, in cases of snake-poisoning; and such cases are, it may be remarked, generally very prone to be characterized by more than usual

violence. It must not, however, be inferred from this statement that the morbid action always spreads from the point originally attacked; for, although there is unquestionably a very strong tendency to this, yet there are numerous exceptions to it. In some cases this limitation is due to the nature of the disease itself; in others it depends upon the deposit of plastic matter; while in a third series of cases it is owing to the structure of the overlying tissue, as, for example, in the periosteum, which often serves to protect the bone which it surrounds from the encroachment of disease of the soft parts.

One of the most common modes in which inflammation propagates itself is by *continuity of structure*. The morbid action, once begun, easily passes along the tissues in which it originated, often spreading rapidly over a large extent of surface, similarity of structure and function favoring its march. By continuity of surface an erysipelas of the skin, perhaps not larger at its commencement than half a dime, frequently in a few hours diffuses itself over an entire limb, or even the greater portion of the body. In the same manner inflammation is liable to be propagated along the mucous canals, as is exemplified in the tonsillitis, croup, and other affections of the throat and air-passages, and in the various diseases of the stomach, bowels, and genito-urinary apparatus. In duodenitis the morbid action may readily extend along the choledoch and hepatic ducts to the liver; and in gonorrhœa nothing is more common than for the disease to spread along the seminal passages to the epididymis and testis.

Secondly, inflammation may be propagated by *contiguity of structure*. A phlegmonous erysipelas of the skin has a tendency not merely to spread over the neighboring surface, in consequence of its similarity of structure and function, but also in depth, thereby involving connective tissue, aponeurosis, muscle, and, in short, every other texture within its reach. The tissues mainly concerned in the enterprise are the vascular and connective, the peculiar structure of which renders them highly favorable for the propagation of the morbid action. An inflammation, beginning in the conjunctiva, often in its progress involves the entire eye, simply from the intimate manner in which its different tunics are superimposed upon each other. In the bowel and other mucous canals the same effect is frequently witnessed. In pneumonia, especially in the more violent forms, the disease is rarely confined to the parenchymatous substance, but is almost sure eventually to spread to the pleura and bronchia. In orchitis, although the inflammation is primarily seated in the tubular structure of the epididymis and testicle, it is by no means uncommon for it to extend to the albugineous and even to the vaginal coat. An inflammation of the synovial membrane of a joint often spreads, by virtue of the same law, to the articular cartilage and the head of the bone beneath, contiguity and intimate connection favoring here, as elsewhere, the propagation of morbid action.

Thirdly, the extension may be effected through the agency of the *veins* and *lymphatics*. Of the former a good example is afforded by what occasionally happens in venesection, where, apparently from the use of a foul lancet, the inflammation sometimes spreads from the little wound in the vessel, at the bend of the arm, as high up as the right auricle of the heart; and of the latter by what occurs in chancroid, where the poison, taken up by the absorbent vessels of the penis, is conveyed by them to the glands of the groin, where it causes a painful swelling, constituting what is termed a bubo. In dissection wounds the absorbent vessels always serve as vehicles for the transmission of the peculiar poison which gives to these lesions their characteristic features. For a short period after the inoculation the poison is apparently latent, when its effects show themselves by one or more red lines extending up the limb as far as the axillary glands, whence, as from a common centre, its injurious impressions are radiated over the whole system.

Of the extension of inflammation by *nervous agency*, or sympathy, a familiar example is afforded in parotitis. In this disease, which attacks chiefly young subjects, the inflammation often suddenly leaves the organ originally involved, and fastens itself upon the testicle, which is thus compelled to bear the whole onus of the morbid action. Of the precise manner in which this transfer is effected nothing is known. As there is no direct nervous connection between these structures, the only plausible conjecture is, that it is brought about by the operation of sympathy, although of the nature of this operation it is impossible, in the present state of the science, to form any correct idea. A similar relationship exists between the mamma and the uterus, the stomach and the lungs, and between the stomach and the brain, or, rather, between the former organ and the arachnoid membrane.

Finally, inflammation may be propagated by the *blood*. This fluid, as will be more fully explained by and by, undergoes various changes in this disease, of which the most important is an increase of fibrin and colorless globules, with a strong tendency of these

substances to adhere to the sides of the vessels as they are propelled along with the general circulating mass. The blood, thus altered in its properties, leads to obstruction of the capillaries in different parts of the body, thereby establishing foci of morbid action. It is in this manner that metastatic abscess, or what is now known as pyemia, is occasionally produced, as is proved by the fact that the aggregation of the colorless corpuscles into small masses, and their adhesion to the walls of the vessels, not only diminish the rapidity of the circulation, but favor the formation of thrombi and the production of embolism.

3. VARIETIES OF INFLAMMATION.

With the exception, perhaps, of the epidermis, the hairs, and the nails, there is no part of the body which is not susceptible of inflammation and its consequences. The reason why these structures are usually considered incapable of this process is our inability to demonstrate in them any bloodvessels, nerves, and lymphatics, the great and essential elements of organization in the more elaborate and complex tissues. Notwithstanding this, it is extremely difficult to unite in so sweeping a conclusion, when we reflect upon the fact, of which daily observation furnishes examples, that these external coverings undergo various lesions of forms, size, color, and consistence, which can only be explained on the assumption that they are the products of inflammation, modified by the nature of the affected parts. There are other structures, as the arachnoid membrane, the cornea, and some of the cartilages, in which it is impossible to detect vessels, and yet no one would doubt for a moment, on this account, that they are incapable of disease. No exception should, therefore, in my opinion, be made, as it respects the possibility of the occurrence of inflammation, even in regard to the cuticle, the hair, and nails.

The susceptibility of a part to inflammation is, as a rule, in direct proportion to the amount of its vascular and nervous endowments, the importance of its functions, and the nature of its exposure. Hence it is found to be most common in the skin, connective tissue, mucous and serous membranes, joints, lungs, liver, kidneys, bladder, urethra, ovaries, and uterus. The only exceptions to this law are the brain and heart, which notwithstanding their incessant labor, the excessive delicacy of their organization, and their universal sympathetic relations, are comparatively rarely the subjects of inflammation. In the thyroid body, the salivary glands, the pancreas, the prostate, and the spleen, the voluntary muscles and their tendons, the nerves, vessels, fibrous membranes, and even the bones, the disease is also uncommon, although several of these structures are sufficiently prone to inflammation as it manifests itself in certain forms of syphilis, scrofula, and rheumatism. It is easy to see why the skin should be so frequently affected, when we reflect upon its vast extent, its wonderful vascularity and nervous endowments, its sympathy with the brain, lungs, stomach, and, in fact, almost every organ in the economy, and its constant exposure to all kinds of injurious impressions. For the same reason it is not difficult to account for the frequent occurrence of pneumonia, hepatitis, nephritis, and inflammation of some of the other viscera. The connective tissue, although less highly organized than the skin, is yet a frequent subject of disease, inasmuch as it is the great link by which the various textures are connected together, and the means of transmission of the vessels and nerves from one part to another. The functional activity alone of some of the organs affords a ready key to their liability to inflammation. Thus, the genital organs are almost exempt from disease until the age of puberty, when, their slumbering season being over, and their fretful life having begun, they are extremely prone to morbid action, both common and specific.

The progress of inflammation exhibits much diversity, being at one time rapid, at another slow; hence the distinction into *acute and chronic*. An acute attack is one which, running its course swiftly, is characterized by well-marked symptoms, as is seen, for example, in tonsillitis consequent upon a severe cold, where, in the space of a few days, the affected gland acquires a large bulk from vascular engorgement and interstitial deposits, attended with great local and constitutional disturbance. Force and rapidity of action are its distinguishing features. Chronic inflammation, on the contrary, is marked by comparative slowness and feebleness of action; the attendant phenomena are also less bold, although there is generally a decided tendency to effusion. It may be the sequel of an acute attack, or occur as a primitive affection, existing, perhaps, for a considerable period without being discovered, owing to the absence of the usual diagnostic signs. Once in this condition, it may last almost for an indefinite time, as is exemplified in certain cases of gleet, leucorrhœa, tonsillitis, osteitis, arthritis, otorrhœa, and ophthalmia.

In addition to the terms acute and chronic, so frequently employed in surgical nomenclature, there are certain expressions in use to designate the degree of the morbid action, as, for example, acute when the action is very intense, subacute when it is comparatively mild, and passive when it is very sluggish, or indisposed, as it were, either to advance or to recede, and accompanied, perhaps, by inordinate congestion of the vessels, especially of the veins, with little, if any, pain, and no marked constitutional disturbance.

Inflammation is said to be *healthy* or *unhealthy*, according as it manifests a tendency to restoration or to mischief. It would be erroneous to regard inflammation always in the light of a disease, since it is the means which nature must necessarily employ whenever she repairs an injury that has given rise to it. It is only when the process proceeds, as it were, blindly, that it is likely to be productive of harm by overpowering the part and system. An incised wound, in a sound constitution, will, if properly managed, heal promptly by union by the first intention; whereas, if the reverse be the case, its edges will be sure to separate, and, suppuration taking place, a long time may elapse before the object is fully attained. In the one case the action is said to be healthy, in the other unhealthy; and it will generally be found that the nature of the action is a true index of the condition of the part and system; as the latter is, so will be the former. There are of course exceptions to this law, but they are infrequent and unimportant.

There is a form of inflammation known as the *irritable*, but which in reality does not differ materially from unhealthy inflammation. The best illustrations of it occur in strumous ophthalmia, in ulcers of the extremities, in rupia, and in chronic tonsillitis, bronchitis, dysentery, cystitis, urethritis, and orchitis. It evidently depends upon an exaltation of the natural sensibility of the affected structures, aggravated by an unsound state of the nervous system.

Inflammation may be *common* or *specific*: common, when it proceeds from ordinary causes; specific, when it is produced by some peculiar poison, as that of gonorrhœa, syphilis, or smallpox. A more important distinction is that certain inflammations are capable of appearing only in certain tissues. Thus, erysipelas is generally a disease of the skin; in rare instances it involves the mucous membrane of the mouth and throat, and, perhaps, also the peritoneum and pelvic veins, as in lying-in females; but it never, so far as can be ascertained, fastens itself, as a primary affection, upon the muscles, aponeuroses, nerves, arteries, bones, cartilages, or internal viscera. Gout and rheumatism have a special fancy for the joints and fibro-serous textures; secondary syphilis, for the skin and fauces; tertiary syphilis, for the bones and periosteum; scrofula, for the lymphatic glands; and carcinoma, for the glandular organs, as the mamma, uterus, and liver. Finally, there are certain diseases, as smallpox, syphilis, and scarlatina, which occur, as a rule, only once in the same person.

Finally, inflammation may be *latent*, or fail to reveal itself by the ordinary phenomena. Such an inflammation is always to be dreaded, because, owing to its insidious character, it is extremely liable to be overlooked. A striking illustration of this form of disease is afforded by the glands of Peyer in typhoid fever, the inflammation and ulceration of which constitute the anatomical lesions of that formidable malady. Patients thus affected seldom complain of pain, or, indeed, of any other suffering directly referable to these bodies, even when the morbid action is so extensive as to induce perforation of the bowel. Latent pneumonia is sufficiently common; and abscesses of the spine and other parts of the body often make great havoc before their true nature is even suspected.

4. TERMINATIONS, EVENTS, OR CONDITIONS OF INFLAMMATION.

Although inflammation is generally said to have various terminations, it will be found, upon strict inquiry, that these amount only to two, all the rest being so many states, conditions, or events of the process. This distinction is real, not imaginary, and therefore of no little practical value. Philosophically speaking, there are only two terminations of the morbid action, the one being in health, the other in the death of the parts. The former may occur by delitescence and resolution; the latter, by ulceration and gangrene. All deposits, whether serous, plastic, purulent, or sanguineous; and all changes of structure, whether they consist in softening, induration, contraction, or thickening, are to be viewed simply as so many products, effects, or results of inflammation, without necessarily involving a suspension of the process itself. This indeed may still go on, sometimes even for an indefinite period, and thus produce additional changes, more serious, perhaps, in their consequences than those which attend the act in its earliest stages. In suppuration, for example, the inflammation does not generally end the moment matter forms, or as

soon as the pyogenic crisis has been fairly attained; instead of this, it proceeds in a modified state, accompanied by ulceration, or still further deposits. The same remarks are applicable to the exudation of plasma, and even of serum, the latter of which may be regarded as one of the processes employed by nature to deplete the inflamed tissues; in this, however, she generally succeeds only by degrees, as is shown by the fact that the disease often continues for a considerable length of time after the drainage has commenced. Blood, either perfectly pure, or variously combined with the secretions of the affected surface, may be poured out quite freely, and yet the morbid action continue as vigorously as before, as is exemplified in dysentery and other hemorrhagic forms of inflammation. There is, therefore, really no such thing as a termination of inflammation in effusion of serum, deposit of plasma, or the formation of pus. These events occurring, the morbid action may still go on, merely modified by the influence exerted upon it by the attendant secretion or the nature of the morbid product.

The nomenclature of inflammation has been much simplified in modern times. As it now stands, it is based essentially upon the anatomy of the affected tissue, structure, or organ, the term itis being merely added to the name by which the part is generally known, as sclerotitis, cystitis, laryngitis. Sometimes, however, the old expressions are retained, as quinsy for inflammation of the tonsils, ophthalmia for inflammation of the eye, and gonorrhœa for inflammation of the urethra.

SECT. II.—ACUTE INFLAMMATION.

The symptoms of inflammation naturally divide themselves into local and constitutional; or those furnished by the part and those afforded by the general system.

1. LOCAL SYMPTOMS.

The most prominent external symptoms of inflammation have been known from an early period of the profession. They are tersely stated by Celsus as "rubor, calor cum tumore et dolore." The knowledge, however, of the Roman physician of inflammation was extremely imperfect, and it was not indeed until some time after the commencement of the present century that the subject began to be studied in its relations with the different organs and tissues of the body. Bordeu, Carmichael Smith, and Bichat, by laying the foundation of general anatomy, paved the way to a more comprehensive acquaintance with the nature and seat of morbid action, and were thus instrumental in revealing an amount of light, the beneficial effects of which can even yet be hardly foreseen. They show what might, a priori, have been anticipated, that the phenomena enumerated by Celsus, as characteristic of inflammation, are liable to great and constant variations, according to the nature of the affected structure, and that the most violent morbid action may often be present, and yet nearly all of these phenomena be absent. Hence, at the present day, too much stress cannot be laid upon disordered function, inasmuch as this is frequently the only symptom that is at all appreciable, especially in inflammation of the internal organs. Modern research has shed important light upon the condition of the capillary vessels and their contents, as well as upon the condition of the cells in inflammation, and has enabled us to explain many phenomena that were previously obscure and mysterious in regard to the more intimate nature of the process.

1. *Discoloration.*— The discoloration of an inflamed part varies from the slightest increase of the natural hue to the deepest purple, according to the character of the affected tissues and the intensity of the morbid action. It is always, other things being equal, most distinctly marked in those structures which are very vascular, while in such as have comparatively few vessels it is either entirely wanting, or present only in a faint degree. It is a prominent phenomenon in inflammation of the skin and mucous membranes, connective tissue, lungs, pleura, spleen, kidneys, and peritoneum; structures which are distinguished by their great vascularity, and by the large amount of blood admitted into them in disease. On the other hand, there is but little discoloration in inflammation, however intense, of the tendons, cartilages, bones, fibrous envelops, brain, nerves, heart, and voluntary muscles. In inflammation of the arachnoid membrane the only evidence of disease observable after death is effusion of serum or of serum and plasma; there is no trace of vascularity, and yet the morbid action has been sufficient to destroy life.

The rapidity with which the discoloration of inflammation advances is greatly influenced by the severity of the morbid action, and, above all, by the activity of the circulation of

the affected structures. In general, however, it proceeds rather slowly, keeping steady pace with the gravescent action ; advancing from rose to red, from red to purple, or from purple to black, as when the part is about to mortify. It is always most distinct at the focus of the inflammation, from which it gradually recedes until, in most cases, it is insensibly lost in the natural hue of the surrounding healthy structures. Occasionally, as in erysipelas of the skin, as well as in some affections of the mucous membranes, the line of demarcation is very abrupt, the diseased surface exhibiting a red and well-defined circle.

The discoloration varies not merely in degree, but also in character, thereby throwing, not unfrequently, important light upon the diagnosis of the case. Thus, it may be scarlet, as in the skin, throat, and bowels ; lilac or bluish, as in the sclerotica and the fibrous envelops of the muscles ; brick-colored, grayish, or brownish, as in iritis ; yellowish, as in erysipelas, especially when this disease is associated with derangement of the biliary secretion ; of a copper hue, as in the eruptions of secondary syphilis ; purple, as in the edges of a scrofulous ulcer ; livid, as in violent tonsillitis ; black, as in mortification. These varieties of color, in these and other structures, are dependent, partly upon the organization of the affected tissues, partly upon the nature of the inflammation itself, and partly upon the amount, degree, or intensity of the morbid action.

In extent the discoloration varies, from the smallest speck, perhaps not larger than a pin's head, to a surface occupying many inches, if not several feet in diameter, as in erysipelas, which sometimes involves the greater portion of the body. When this is the case, the discoloration is said to be diffuse ; it is arborescent, when the vessels upon which it depends are arranged in dendritic lines ; punctiform, when it occurs in little dots, or points, as in some of the inflammations of the serous and mucous membranes ; linear, when it presents itself in a distinct line, as in phlebitis and angeioleucitis ; maculiform, when it assumes the appearance of a blotch or of an ecchymosis. In the latter case, as well as in the punctiform variety of discoloration, the morbid hue is due to an actual extravasation of blood, consequent upon the rupture of some of the capillary vessels of the part.

To be of value as a diagnostic sign of inflammation, the discoloration must be permanent, not transient ; advancing and receding with the morbid action ; disappearing under pressure, but reappearing the moment the pressure is taken off. The blush of shame vanishes in an instant, with the excitement that produced it ; the hectic flush upon the cheek of the consumptive merely denotes the existence of the fever which succeeds the afternoon's rigor ; they are very different from the discoloration which marks the rise, progress, and termination of inflammation. Besides, the latter is usually associated with other symptoms, as heat, pain, swelling, and disordered function ; phenomena sufficiently distinctive, in every case, to prevent error of diagnosis. More or less discoloration generally remains, in a modified form, for some time after the inflammation has ceased.

The immediate cause of the changes of color in inflammation is a preternatural afflux of blood. In the normal condition of the organs and tissues there are hundreds and thousands of capillary vessels which are too minute to admit of a sufficiency of red globules to render them visible, but which, under the influence of irritation, become distended to such a degree as to display themselves in every direction. It is in this manner that the discoloration of the affected structures is brought about, often in an instant, as is witnessed, for example, in the conjunctiva, when a particle of foreign matter lodges upon the cornea ; and what occurs here unquestionably occurs, under similar circumstances, in other structures. It is only in reparative inflammation, or in inflammation concerned in rebuilding wasted tissues, that new vessels are formed ; never in ordinary inflammation.

2. *Pain.*—Pain, like discoloration, is one of the most constant symptoms of inflammation, usually setting in early in the disease, going on steadily increasing until the morbid action has attained its maximum, and then gradually abating, as the disease recedes, until it is insensibly lost. The subject of pain presents several points of interest, which, as they have a practical importance, should be well understood by the surgeon.

Pain varies in degree from the slightest change in the normal sensibility of the part to the most excruciating agony, according to the nature of the affected structure, and the intensity of the morbid action. Doubtless idiosyncrasy also exerts an important influence, for it is well known that what causes pain in one individual, causes little, if any, in another. Few persons suffer much from the application of a blister, but occasionally, although it may be retained only for a few hours, it is productive of the most exquisite torture. Such a result can only be explained by assuming that there is an idiosyncrasy, or a difference in the nervous organization of our patients. The same remark is true in regard to the effects of injury. As a rule, the pain is greatest at the focus of the inflammation, and

fixed in its situation, but sometimes it darts about in different directions; is increased by pressure, motion, and change of posture; and rarely intermits, although it often remits, especially in the morning and in the early part of the forenoon.

In regard to the character of the pain, there is great diversity, so much so, indeed, that it is often possible, from this circumstance alone, to form a tolerably correct idea of the seat, and even of the nature, of the inflammation. Thus, in the pleura it is sharp and lancinating; in the connective tissue, acute and throbbing, as is exemplified in boil and carbuncle; in the liver and lungs, obtuse and heavy; in the testis, sickening; in the skin, prurient, itching, or smarting; in the bones, dull and gnawing, as if insects were feeding upon the part; in the urethra, scalding or burning; in the conjunctiva, gritty and itching; in the teeth, throbbing, beating, or pulsatile. When inflammation is about to terminate in mortification, the pain generally becomes hot and burning.

Pain is sometimes felt at a point more or less remote from the seat of the morbid action, and for this reason does not always serve to denote its existence. In coxalgia, the earliest and most prominent symptom usually is severe pain in the knee, and it has often happened, especially in the hands of ignorant and inexperienced practitioners, that the latter has been leeched, cupped, and blistered, when all this care should have been bestowed upon the hip. In inflammation of the bladder, ureters, and kidneys, a prominent symptom is uneasiness in the head of the penis; and in hepatitis considerable suffering is occasionally felt in the right shoulder. In certain cases of carcinoma of the uterus, the pain, instead of being located in this organ, is situated in the mamma, the sides, the back, groins, or thighs. It is not always easy to explain these occurrences; but, in general, they are dependent either upon continuity of structure, as in the case of the urinary passages, or upon reflex action, as in coxalgia and hepatitis. In the latter, something may possibly be due to disorder of the intercosto-humeral nerves.

It is worthy of note that the pain is generally much more violent in inflammation of the covering of an organ than in inflammation of its proper substance. A pleuritis is always attended with severe local distress, whereas very little, if any, is experienced in pneumonitis. In inflammation of the parenchymatous structure of the liver, great disorganization may take place, and yet the patient be entirely ignorant of the fact, as far as pain is concerned; but when the fibro-serous envelop of the organ is mainly implicated, violent suffering is always a prominent symptom. The same law obtains even in inflammation of the brain and its membranes. Pain, especially in chronic inflammation, as gout and rheumatism, is greatly influenced by atmospheric vicissitudes, as is evinced by the fact that it is always more severe in damp than in dry weather. Nocturnal exacerbations are very common, if not constant, in inflammation of the bones and joints, particularly in syphilitic subjects.

A correct distinction should be drawn between the pain of inflammation and the pain of spasm, as it exercises an important influence upon the treatment of the case. The former, as previously stated, is gradual, not sudden, in its attack; persistent, not intermittent; increased by motion, pressure, and posture; and is, moreover, generally accompanied by more or less febrile disturbance, and other evidences of indisposition, plainly marking its character, to say nothing of the history of the case, which usually furnishes important light in regard to the diagnosis. In spasm, the pain comes on suddenly, and, after having continued for a short time, intermits, or entirely disappears, only, however, to return again, and to pass through the same course; in a word, it is paroxysmal, coming suddenly, and going suddenly; relieved by pressure, and nearly always attended with eructations, and rumbling noises in the bowels, supposing the case to be one of colic; there is no fever—indeed, generally no constitutional excitement of any kind—and there is also an absence of the other local symptoms of inflammation, as heat, discoloration, and swelling.

In neuralgia the pain is sharp and lancinating, often darting through the parts with the rapidity of lightning, or like an electric shock; accompanied by a sense of soreness or aching, and generally aggravated by pressure. It is usually paroxysmal, coming on perhaps once every day, lasting a few hours, and then going off gradually, or even suddenly, to reappear about the same time the following day; it is, in fact, generally an intermittent disease, with a distinct interval of freedom from pain, resembling, in this respect, an ordinary intermittent fever, and having often, like it, a miasmatic origin. The pain, moreover, is not always fixed, but is at one time here, and at another time there, generally in the course of a sentient nerve.

Severe pain, especially in a nervous, irritable person, is always a formidable occurrence, as it exhausts and depresses the powers of life, and is sure, if not speedily combated, to occasion serious, if not fatal, mischief. The rule, therefore, is to arrest it

promptly, and at all hazards, before the disease, of which it is a symptom, has committed any serious ravages.

A sudden disappearance of pain, unless occasioned by the use of anodynes, is generally denotive of danger, as it implies a termination of the morbid action in the death of the affected structures. The occurrence should, at all events, excite suspicion, and lead to careful investigation. An individual, for example, has been the subject of strangulated hernia; the constriction has lasted for several days, and has been characterized by severe suffering, both local and general; suddenly the pain ceases, and the patient flatters himself that he will soon be well. The surgeon, however, comes to a widely different conclusion; for the sunken features, the clammy skin, the feeble, flickering pulse, the incessant hiccough, and the trembling hand, but too plainly foreshadow the approach of death from mortification of the bowel.

Pain is not always present, even although the inflammation may be extremely violent. In typhoid fever, a disease attended with inflammation of the glands of Peyer, often terminating in extensive ulceration, there is generally an entire absence of this symptom, from first to last, unless the case is followed by perforation of the bowel, and an escape of its contents into the peritoneal cavity. In pneumonia there is frequently no pain whatever; and the same is true of inflammation of some of the other viscera. In scrofulous affections of the spine, particularly in those forms of it known as Pott's disease and psoas abscess, pain, properly so called, is one of the rarest phenomena, especially in the earlier stages of their progress. A painless inflammation is peculiarly dangerous, inasmuch as it is very liable to be overlooked by the professional attendant, particularly by one who is in the habit of placing undue confidence in the ordinary phenomena of the disease.

The immediate cause of pain is the compression experienced by the nerves at the seat of the morbid action by the dilated vessels, but more especially by the inflammatory deposits, thereby interrupting the transmission of their peculiar fluid, which thus accumulates and explodes at the point of obstruction, like the fluid in an electric battery. The nerves themselves necessarily participate in the disorder, sharing the same fate as the other tissues, and so increasing the suffering.

Of the intimate nature of pain nothing is known beyond the fact that it consists of a peculiar mental perception, dependent upon a healthy state of the brain. There must be consciousness, otherwise there cannot be any cognizance of the mischief wrought by disease. Of this a convincing proof is afforded in what occurs in apoplexy and paraplegia, in which the most violent inflammation may be set up, both in the internal and the external structures, and yet the patient be utterly insensible of its presence. The brain and nerves being crippled, the latter are unable to convey, and the former to receive, painful impressions.

Although pain is a great evil, it is extremely fortunate that it is so generally present in inflammation, inasmuch as it serves to warn the patient of his danger, and usually supplies the practitioner with important information respecting the nature and seat of the morbid action. How many persons formerly perished of typhoid fever simply because there was no pain to guide the physician to the true lesions of the disease!

What is termed *throbbing* is a peculiar form of pain, generally denotive of the approach of suppuration. It is, however, sometimes felt at an early stage of the morbid action, especially when it involves the fibrous, fibro-serous, and osseous tissues. It is generally dependent, in the first instance, upon an unusually crowded state of the capillary vessels, impeding the flow of blood, and afterwards, when the disease is more fully developed, also upon the presence of inflammatory deposits. Posture exerts a powerful influence upon its production, as is evinced in whitlow, odontalgia, and common furuncle. In the first of these affections the pain is increased a hundredfold, almost in an instant, when the hand is lowered; a decayed tooth that is free from pain in the day, while the patient is walking about, aches intensely the moment he lies down at night; and a boil on the buttock, which causes hardly any uneasiness during recumbency, throbs violently when the body is erect.

3. *Swelling.*—Swelling is seldom entirely absent in inflammation of the external parts of the body, but very generally in that of certain internal structures, however violent or extensive the morbid action. Under the latter head may be enumerated, in particular, the fibrous and serous membranes, tendons, cartilages, bones, vessels, and nerves, along with most of the different viscera. The mucous membranes also may suffer in this way; the principal points where swelling is liable to occur, as a result of inflammation, are the conjunctiva, glottis, tonsils, and vulva, for the reason that these parts are largely supplied

with lax cellular material, which, wherever it exists, readily admits of infiltration of serous and other fluids. Hence it is that swelling is generally so conspicuous in inflammation of the subcutaneous and intermuscular connective tissues, especially in the extremities, and sometimes even in the head, as is noticed in the more severe forms of erysipelas, where the scalp and face are occasionally puffed up to an enormous extent, frightfully disfiguring the features.

The progress of the swelling varies; in general it is gradual, beginning early in the inflammation, and increasing steadily until the morbid action has attained its height; even then, however, it does not always stop, but often continues until the vessels have parted with their more fluid contents, which sometimes occurs only after the disease has begun to decline. Occasionally, however, the swelling is most rapid and extensive, spreading, in a short time, over an entire limb, or even the greater portion of the body. The best examples of this occurrence are witnessed in certain injuries, as compound fractures and dislocations, phlegmonous erysipelas, and the inflammation consequent upon the application of steam, alkalies, acids, and certain animal poisons, as that of the rattlesnake.

The swelling varies in its character; thus it may be soft or hard, transient or protracted, beneficial or injurious. A soft swelling is usually denotive of serous effusion; a hard one, of a deposit of plasma, or of the more solid elements of the blood. A transient swelling is generally less prejudicial than a protracted one, as it is less likely to interfere with the restoration of function. Swelling often proves beneficial, inasmuch as the effusion upon which it depends is a means of depletion employed by nature to relieve inflammatory action; it answers, in fact, the same purpose as a blister or a topical bleeding. When, however, the deposit is very large, or composed essentially of solid material, it may produce immense harm by compressing the capillary vessels and thus interfering with the transmission of their contents; in other words, the effusion chokes the parts, and thereby causes fatal constriction. In swelling of the conjunctiva, technically called chemosis, the matter poured out often compresses the vessels of the cornea in such a manner as to induce gangrene of this membrane; and a like result not unfrequently follows phlegmonous erysipelas of the limbs and scrotum. Swelling may prove injurious in another way; by acting obstructingly, as in œdema of the glottis, which may cause death by preventing the ingress of air into the lungs. A similar effect may be produced by inordinate tumefaction of the tonsils. A swollen perineum may compress the urethra, and thus occasion retention of urine.

The immediate cause of swelling is twofold: first, engorgement of the capillary vessels, and secondly, and mainly, effusion of serum and plasma; to which, in the more severe forms of inflammation, may be added pus and blood, the latter of which is sometimes poured out in considerable quantity.

4. *Heat.*—An increase of heat is one of the most common effects of inflammation, and hence a valuable symptom of the disease. A good illustration of this occurrence is observed in tonsillitis, gastritis, pneumonia, and the so-called fevers, in which there is often a remarkable heat of the breath; and also in many of the external varieties of inflammation, where the change is rendered apparent both by the sense of touch and by the rapid evaporation of our applications. The scalding tear in inflammation of the eye is an evidence of the same fact.

The degree of heat, emitted in the act of inflammation, was at one time supposed never to exceed that of the blood in the heart and large vessels. The researches of John Hunter strikingly countenanced this opinion. In operating upon a man for the radical cure of hydrocele, the temperature of the vaginal tunic immediately after the withdrawal of the fluid was ascertained to be 92°. The cavity was now stuffed with lint, and the next day the thermometer stood at 98¾°, thus showing an increase of six degrees and three-quarters, which must have fully equalled the heat of the blood in the heart and large vessels of the patient. In repeating the experiment subsequently upon a muscular wound in the side of a dog, and upon the vagina of an ass, irritated by a solution of bichloride of mercury, he found no difference whatever, before or after the occurrence of inflammation in the temperature of the parts. Hence, he naturally concluded that the extrication of heat during the progress of this morbid process was either very slight or altogether inappreciable. Observations, however, made since the time of the English philosopher, conclusively show that there is frequently, if not generally, a decided increase of temperature in the inflamed structures; and, although this increase may not render the temperature of the part equal to that of the heat of the blood in the heart, yet it is none

the less real and positive. It is well known that the outskirts of the body, as the feet, hands, and ears, are habitually cooler than the trunk, head, and upper portions of the extremities, because they have naturally a more feeble circulation : hence, in inflammation, although their temperature may not reach 98° of Fahrenheit, yet if there be any elevation of heat over and above what these structures enjoy in the healthy state, it is to be considered as an actual augmentation. That this is the fact, in all the more severe forms of inflammation, personal observations, many times repeated, fully satisfy me. In erysipelas of the skin of the trunk, in urinous infiltration of the scrotum, in acute abscess, in tonsillitis, orchitis, bubo, and other affections, I have again and again seen the mercury arise above 100°, and in some instances even as high as 105°, 106°, and 107°. The oviduct of a frog ready to spawn is two degrees warmer than its heart ; and Professor Dunglison saw the temperature of the uterus during labor rise as high as 106°. From a consideration of facts such as these it is impossible to avoid the conclusion that there is generally an elevation of heat in inflammation, in whatever part of the body situated, provided the concomitant action is not too slight, or too limited in extent. A marked increase, followed by a decided decrease, of temperature, follows the section of certain nerves, notably of those belonging to the sympathetic system, in the structures supplied by the wounded cords.

The nature of animal heat is not sufficiently understood to justify us in expressing any decided opinion regarding the cause of its increase in inflammation. It may be supposed, however, to be mainly due, first, to the friction which the blood experiences in its passage through the vessels, not only in the inflamed parts, but in the system at large ; secondly, to the oxidation of the carbon and other material introduced into the system in our food ; and, thirdly, to the rapid union of the oxygen of the air with the red particles of this fluid as it is propelled along in its turbulent course. The influence of an accelerated state of the circulation upon the production of animal heat is well exemplified in what occurs in ordinary exercise when the feet are cold. A rapid walk under such circumstances in the open air soon equalizes the circulation, and sends the blood, loaded with oxygen, to every part of the body, warming it as it rushes on. If a horse be rode swiftly round the race-track, his whole body becomes intensely heated, and the blood surcharged with fibrin and colorless globules ; both evidently the result of the increased friction of the blood against the coats of the vessels, and the rapid union of the oxygen of the air with that fluid. Irritating applications, as spirits of ammonia, blisters, sinapisms, and embrocations, by inviting a preternatural afflux of blood to the affected part, produce an analogous effect, accelerating the circulation and causing an elevation of temperature. The augmented heat of the uterus during parturition can only be explained on the supposition of an increased activity of its vessels, approximating to a state similar to that which obtains in inflammation, although not identical with it. During the growth of the antler of the deer and of other animals there is always a marked elevation of temperature ; and phenomena of a similar kind are often witnessed during the development of malignant and other tumors. All these occurrences bear directly upon the question under consideration, if they do not positively serve to establish its truth.

5. *Tension.*—A sense of tension, pressure, weight, or fulness is a prominent symptom in inflammation, and often greatly aggravates the local and general distress. It is particularly conspicuous in inflammation of the denser structures, as the fibrous membranes, tendons, and cartilages, but it is also not unfrequently very severe in the more lax, as in the mucous membranes and the connective tissue. The immediate cause of the tension is the presence of effused fluids, as serum, lymph, and pus, which thus compress and constrict the affected parts. It is not improbable that mere congestion, or inordinate distension of the capillary vessels, may produce a similar effect. In either event, however, it is necessary that the parts should be more or less severely inflamed, and abnormally sensitive ; otherwise the feeling cannot arise, as is proved by the fact that mere distension, however considerable, will not induce it, as is exemplified in anasarca of the lower extremities, the penis, scrotum, and eyelids, where the accumulation is often enormous, and yet no sense of tension is experienced during any period of the attack.

Great tension sometimes occurs in inflammation of the viscera, as the liver, spleen, kidney, and prostate gland. When combined with throbbing, it is generally denotive of incipient suppuration. In orchitis, tension is usually a prominent symptom. It is seldom, if ever, absent in boils, carbuncles, erysipelas, and paronychia. Occasionally tension seems to be a purely nervous phenomenon, as, for example, in what is called sick-headache.

6. *Functional Disorder.*—Disorder of the functions of the affected part is generally a most important symptom, as it is often present when all, or nearly all, the other phenomena are absent. It manifests itself in various ways, as well as in various degrees; at one time in increased sensibility or irritability, at another as a suppression, alteration, or augmentation of the natural discharge, and now as an abolition of some special sense; at one time as the slightest possible departure from the normal action of the part, and at another as a total suspension of it.

An increase of *sensibility* is one of the most common effects of inflammation. In peritonitis, gastritis, and enteritis, the sensibility of the affected structures is often so great as to render the slightest pressure of the finger a source of profound distress; and it is for the same reason that, under such circumstances, the weight even of a sheet is sometimes almost intolerable. Similar effects are noticed in some of the external diseases, as in boil, carbuncle, erysipelas, and in inflamed hemorrhoidal tumors, which are frequently the seat of the most exquisite tenderness, hardly exceeded by that which attends an inflamed eye. Parts which are devoid of feeling, or nearly so, in the sound state, such as ligaments, tendons, bone, and fibrous membranes, generally become exceedingly sensitive in inflammation. The change in question is diagnostically of great importance, inasmuch as it usually enables us to distinguish readily between inflammatory and spasmodic affections, the latter of which, as before stated, are often immensely relieved by pressure, which never fails to aggravate the former.

An increase of *irritability* is a very constant phenomenon in all inflammations of muscular parts. In cystitis, one of the earliest and most prominent symptoms is a frequent desire to urinate, arising from involvement of the muscular fibres of the bladder; in gastritis, the irritability of the stomach is so excessive that the organ is incapable of retaining the smallest quantity of fluid, however bland; and in dysentery, the principal suffering is due to the incessant peristaltic action of the colon and rectum, the main seats of the morbid action. An increase of the contractility of the voluntary muscles is very common in fractures and dislocations, in severe sprains, and after amputation, usually manifesting itself in spasmodic twitchings, which can only be relieved by the liberal use of anodynes.

Inflammation produces important changes in the special functions of an organ, sometimes exalting, at other times diminishing or even completely suspending them. In ophthalmia, the eye cannot look at objects, however dim; the moment the effort is made, the lids contract spasmodically, and the smallest ray of light that impinges upon the retina is productive of the greatest distress. In inflammation of the ear, the slightest noise, which in the healthy state would perhaps not be perceived, or which might fall as delightful music upon the tympanum, becomes a source of deep distress; and the sense of hearing is almost destroyed by the buzzing and explosive sounds which succeed the morbid action. In coryza, the sense of smell is abolished; in inflammation of the skin, the sense of touch; in glossitis, the sense of taste. In laryngitis the voice is at first merely altered in its character, but as the disease progresses complete aphonia often ensues. In cerebritis there is generally delirium, followed, if the case passes on to suppuration, by convulsions and coma, the precursors of speedy dissolution.

Another prominent symptom of inflammation, one, indeed, which is seldom absent, is disorder of the *secretions.* Thus, in inflammation of the skin, there is suppression of the perspiration; in hepatitis, of the bile; in nephritis, of the urine. Or, instead of an arrest partial or complete, of these and other secretions, important changes are effected in their composition, or in their physical, chemical, and microscopical properties. In pneumonia, the characteristic symptom is a rust-colored sputum; in dysentery, a discharge of bloody mucus.

The function of *absorption* is often seriously impeded, if not completely checked, in inflammation. The disorder, however, is generally much more conspicuous in the advanced than in the early stages of inflammation, in which this process is sometimes executed, even with a certain degree of vigor, as is demonstrated by the facility with which morphia and other substances are carried into the system when placed upon the skin after vesication by cantharides, ammonia, or hot water. In the more violent grades of inflammation, the function is usually in a state of abeyance, the action of the absorbent vessels being arrested by the morbid deposits. Afterwards, however, as the disease declines, the function of absorption is gradually reëstablished, and then often proceeds with great vigor, rapidly removing the fluids effused during the earlier stages of the inflammation.

It is worthy of notice that while the absorbent vessels, during the height of inflammation, refuse to take up extraneous matter, as, for example, morphia or belladonna, and also

effused fluids, they are often very busy in removing affected textures, even when of a very firm and resisting character. A familiar illustration of this occurrence is afforded in acute abscesses, the natural evacuation of which is frequently accomplished by the agency of the absorbent vessels, where the disease is most intense. In inflammation of the joints, cartilage and even bone often suffer extensively from this cause. There is no doubt that the pressure of effused fluids always greatly influences and promotes the occurrence.

2. CONSTITUTIONAL SYMPTOMS.

Constitutional symptoms do not always attend inflammation. The morbid action may be so mild as to prevent its recognition by the system; it is strictly a local affection, and therefore causes no general resentment. But the case is very different when the disease is severe, or when, even if comparatively slight, it involves an important structure; then the whole frame feels its irritating and depressing effects, and evinces a strong interest in the impending struggle. The group of phenomena thus produced constitutes what is termed inflammatory, symptomatic, or sympathetic fever, and deserves consideration as expressive of the sum of suffering of each particular organ. The period which intervenes between the establishment of the inflammation and the occurrence of fever varies from a few hours to several days, depending upon the nature of the exciting cause, the condition of the patient, the intensity of the disease, and, above all, the importance of the organ attacked. Idiopathic inflammation is generally preceded by depression or a sense of lassitude and uneasiness, attended with headache, pain in the back and limbs, bad taste in the mouth, vitiated appetite, and slight chilliness, alternating with flushes of heat. Sometimes the patient is remarkably desponding, or annoyed with disagreeable dreams, and unpleasant forebodings respecting his recovery. He feels uncomfortably, both bodily and mentally, and is disinclined to exertion. In a word, he is unwell, or in a state intermediate between health and sickness. These phenomena, which are merely the precursors of the fever, which is as yet only in a state of incubation, may be compared, not inaptly, to the fleeting clouds which precede the outbreak of a storm; they appear and vanish for a time, but gradually coalescing, at length assume their allotted station in the chain of morbid changes. When fully established, the fever never intermits so long as the cause which has produced it continues in operation; it, however, generally remits slightly in the morning, and sometimes, although rarely, twice in the twenty-four hours. The vesperal exacerbation, during which the temperature rises to 102° or 103° Fahr., usually sets in late in the afternoon, and persists, with but little alteration, until towards morning, when the excitement relaxes its hold, as if in need of temporary repose to meet the gradually recurring emergency. During the calm which is now present, the patient often falls into a refreshing sleep, his thirst and restlessness subside, and the skin is bedewed with a gentle perspiration. Soon, however, the smothered fire is rekindled, and the same suffering has to be passed through as before, now, perhaps, augmented by the spread of the morbid action, and the development of new sympathies.

The type of the attendant fever varies. In young and robust subjects, and in the earlier stages of the disease, it is generally of a sthenic character, and asthenic under opposite circumstances. Very frequently the symptoms are denotive of great debility from the very commencement of the attack. In some cases both the sthenic and asthenic types are associated with excessive irritability, constituting what is called the nervous form of inflammatory fever.

The nature of inflammatory fever can only be fully comprehended by thoroughly interrogating, as it were, every organ of the body supposed to evince any sympathy with the affected structures. Such an inquiry must, of course, embrace an examination of the heart and arteries, the countenance, skin and extremities, lungs, tongue, stomach, bowels, liver, kidneys, and bladder, together with the state of the muscles, brain, and assimilative powers.

Derangement of the *vascular system* is chiefly denoted by the state of the pulse, the principal characteristics of which are frequency, hardness, fulness, strength, and quickness. The number of beats in a minute ranges from seventy, seventy-three, or seventy-five, the average standard in the healthy adult, to eighty-five, ninety-five, one hundred, or even one hundred and twenty, according to the intensity of the disease and the vigor of the constitution. A hard pulse is firm and resisting, rolling under the finger like a tense cord, as if the blood were sent into it with extreme power; sometimes the artery thrills or vibrates, owing to a partial displacement synchronous with the contraction of the left ventricle of the heart. When the tension is unusually great, it is difficult, even

with forcible pressure, to obliterate the caliber of the vessels. Fulness has reference to the volume of the pulse, which feels as if the artery were expanded beyond its normal size. Strength implies a sensation of preternatural resistance to the finger; while a quick pulse is one in which each beat occurs with great suddenness or abruptness. This quality of the pulse is generally associated with frequency, from which, however, it differs essentially, as the latter has reference merely to the number of strokes in a given time, and not to the rapidity with which the vessel dilates and contracts under the finger. Several of these states of the pulse may be absent, and yet the case be one of great disorder of the vascular system. Their entire coexistence, in fact, is uncommon; perhaps the nearest approach to it is to be found in gout and rheumatism, hepatitis, pleurisy, splenitis, and the commencement of smallpox.

The pulse is often materially modified by the nature and seat of the inflammation and by the idiosyncrasy of the patient. In cephalic affections, it is slow, full, and laboring, in consonance with the oppressed condition of the heart; in peritonitis, it is small, frequent, and wiry, sometimes, in fact, almost undistinguishable; and in acute inflammation attended with internal venous congestion, as in certain forms of fever and injury, it is obscure and apparently feeble, but generally rises under the effects of remedies, or the powers of the system. Idiosyncrasy often singularly modifies the state of the pulse. A middle-aged man, a patient of mine, has a pulse habitually under forty, and other examples of this abnormal condition, equally striking, have fallen under my observation. On the other hand, it may be unnaturally frequent, beating constantly from eighty to ninety in the minute.

Peculiarities like those here instanced, whether the result of disease or of idiosyncrasy, derive a special value from the influence which they must necessarily exert upon our diagnosis and treatment. Thus, in peritonitis, the practitioner, if governed solely by the state of the pulse, without any knowledge of the condition of the system which causes it, would be almost sure to administer stimulants instead of applying leeches and blisters; thereby feeding in place of diminishing the inflammation, and so hurrying on the fatal crisis. A pulse, habitually slow, might, in inflammation, hardly attain the normal standard of frequency, and yet the system might literally be consumed by symptomatic excitement. The surgeon, aware of the possibility of such occurrences, is wide awake, never allowing himself to be thrown off his guard, whatever may happen.

The *countenance*, in inflammatory fever, is generally flushed, and often even unnaturally full, as if it were slightly tumid. The eyes are reddish, suffused, and frequently intolerant of light. The skin is hot and dry, the perspiration being kept in complete abeyance; and the extremities are usually so warm and uncomfortable as to be unable to bear any covering. When the excitement is excessive, the sufferer generally finds it impossible to maintain the same posture beyond a few minutes; he tosses about from side to side, and from place to place, in search of a cool spot.

The *respiratory organs* actively participate in the general disorder. The inspirations are increased in frequency, and are usually performed with a certain degree of labor; various kinds of râles are heard, and cases occur in which there is well-marked evidence of venous congestion.

The *digestive organs* always suffer more or less severely in inflammation. The tongue is variously affected: sometimes it is red and almost clean, but generally it is coated, either with a whitish, yellowish, or brownish fur, contracted, and somewhat reddish at the tip and edges; nearly always dry, and easily protruded, though often a little tremulous, especially when the person is of a nervous temperament. The taste is vitiated, or entirely abolished, the salivary secretion is suppressed, a thick, dark-colored mucus adheres to the lips, gums, and tongue, and there is a disagreeable arid feeling in the fauces and œsophagus. The thirst is intense, and can hardly be appeased by the most frequent and abundant draughts; the appetite, on the contrary, is usually destroyed, and hence the patient often loathes food, in whatever form presented. Nausea and a sense of gastric oppression, sometimes accompanied with bilious vomiting, are common attendants. The bowels are generally constipated, or alternately constipated and relaxed, distended with gas, and somewhat tender under pressure, the alvine evacuations being fetid, and variously altered in color and consistence. Along with this condition of the digestive tube there is usually more or less disorder of the liver, manifesting itself in excess, deficiency, or vitiation of its special secretions. Such a condition is very apt to be present in symptomatic fever consequent upon accidents and idiopathic inflammation in malarious districts. In what manner, or degree, the functions of the pancreas are affected in this disease, we are ignorant. The

probability, however, is that it suffers very much in the same way as the salivary glands of the mouth, which it intimately resembles in its structure and uses.

The changes produced by inflammation in the *renal secretion* relate chiefly to the quantity, color, and consistence of that fluid. In the normal state, the average quantity of urine, in the twenty-four hours, is from thirty-five to forty-five ounces, whereas in inflammatory fever it often does not reach one-half, one-third, or even one-fourth of this amount. Moreover, instead of being of a clear amber hue, as it naturally is, it is commonly of a deep red tint, and surcharged with an unusual quantity of extractive matter, mucus, and lithic acid, the latter of which, in a few hours, always falls to the bottom of the receiver, in the form of brick-colored sediment. The specific gravity of the secretion, varying from 1020 to 1024 in health, is also very much increased, and the odor is often more or less offensive from the presence of various kinds of animal substances. The chlorides, on the contrary, are commonly remarkably diminished, especially when there is much exudation with a tendency to cell growth. During the height of very acute inflammation, the fluid is often slightly albuminous, and even pervaded by tubular casts. A large quantity of urea is occasionally thrown off. Thus, in a case of pyæmia, recorded by Vogel, it amounted, in the twenty-four hours, in the febrile state, to 1235 grains. The excretion of the fluid is seldom much affected, although sometimes it is greatly increased in frequency. In traumatic inflammation, as after fractures, dislocations, and amputations, the bladder is occasionally so torpid as to require the aid of the catheter for the relief of its contents.

The *muscles* are generally the seat of great discomfort in this form of fever. Already during the stage of incubation the patient is harassed with a sense of lassitude, stiffness, and aching or darting pains, which, gradually augmenting in severity, at length constitute a source of great suffering. The pains in the lumbar region are particularly violent; they are always worse at night, and are often so intense as to deprive the patient completely of sleep. His back feels as if it were bruised, broken, bored, or sawed. Not unfrequently every joint is racked with pain, and the whole body is so exquisitely sensitive as to be intolerant of the slightest motion, pressure, or manipulation. It is this distress in the muscles that causes the patient such weary and painful nights, and which induces him to exclaim in the evening, " Oh that it were morning!" and in the morning, " Oh that it were evening!"

The suffering of the *brain* is evinced by a peevish and irritable state of the mind; by loss of sleep; by disagreeable dreams; and by occasional fits of delirium. In many cases there is more or less perversion of special sensation, as is evidenced by the distracting noises in the ears, the intolerance of light, the vitiated taste and smell, and the impairment of the sense of touch.

Finally, the *assimilative* powers being in abeyance, the body is gradually emaciated, and the strength fails in proportion to the impoverished condition of the blood and solids. Every tissue wastes, the fat is absorbed, and the countenance presents a shrunken, attenuated appearance.

Such is the ordinary course of events in inflammatory fever. If the morbid action do not proceed too far, or if the patient be unusually strong and vigorous, recovery is not only possible, but probable. The disease, and, along with it, the fever which it has induced, will gradually subside, the occurrence being announced by a diminution of restlessness, anxiety, and thirst, by a restoration of the moisture of the skin and mouth, and, in short, by a decided improvement in the condition of all the secretions. The sleep becomes more natural and refreshing, the appetite returns, the pulse and temperature descend to their normal standard, and the mind regains its accustomed equilibrium. The cessation of the fever often declares itself by the occurrence, either sudden or gradual, of a profuse sweat, to which the older pathologists applied the term critical, and by a general unlocking of all the secretions. In a word, the clouds which had so long obscured the horizon are once more succeeded by sunshine; disease has vanished, and health is regaining its supremacy.

If, on the other hand, the disease progresses, a downward tendency is gradually witnessed of evil, if not fatal, portent. The symptoms, losing their inflammatory type, now assume a *typhoid* character: the pulse becomes weak, soft, tremulous, and frequent, beating from one hundred and thirty to one hundred and sixty in a minute; the countenance assumes a peculiar shrunken aspect, denominated Hippocratic; the surface is bedewed with clammy perspiration; the extremities are inclined to be cold; the tongue is dry and covered with a brownish or blackish fur; sordes collect upon the teeth; hiccough and twitching of the tendons supervene; and there is rapid emaciation, with corresponding failure of the strength, and low muttering delirium. Recovery is still possible, although

doubtful; a well-directed plan of treatment, or even nature's unassisted efforts, may be sufficient to shake off the oppressive load, and enable the part and system to triumph over the ravages of the disease.

But typhoid fever is not always a necessary consequence of the inflammatory; it may, and often does, exist as an independent affection, coming on early in the attack, perhaps almost immediately after the commencement of the morbid action, and maintaining throughout a well-marked asthenic type. The most common cause of such an event is severe shock or loss of blood, occurring in an unhealthy, broken state of the system, or actual blood-poisoning, from the absorption of decomposing pus, or the operation of some specific virus, as that of malignant pustule, or that generated in the dead human body, and received by inoculation in dissection. In the more severe grades of erysipelas and carbuncle, the fever soon assumes an asthenic character, whatever may have been its original type, the system being speedily overwhelmed by the depressing influence of the morbific agent.

The occurrence of typhoid symptoms early in an idiopathic, specific, or traumatic inflammation, always portends evil, as it is denotive of great and rapid waste of life-power, which neither medicine nor food can, perhaps, successfully counteract. The nervous system is deeply involved in the morbid process; the blood is gradually deprived of its plastic properties; and, nutrition being at a stand, the body soon becomes pale, emaciated, and withered. The mind is early affected, and typhomania is generally a prominent symptom throughout. The vital forces diminish more and more, there is incessant muttering, with picking at the bedclothes, hiccough, and twitchings of the tendons, and the patient is so weak as to be unable to support himself upon his pillow. Exhaustion, in fact, is extreme, and a few hours generally suffice to close the scene.

There is another form of fever which is often seen during the progress of inflammatory affections, and to which the term *irritative* has not inaptly been applied, as it is generally met with in persons of a nervous, irritable temperament or habit of body. The best idea that can be given of it is that it bears the same relation to the nervous system that inflammatory fever, properly so called, sustains to the vascular; that is, the fever in the one case is characterized by irritability, or excess of sensibility, and in the other by plethora, or redundancy of vascular action. We find, accordingly, that in irritative fever there is a lively perception of pain, and an unusual exaltation of sensibility, both of the part and system; the mind is peevish and fretful, easily dissatisfied, and often filled with despondency and unpleasant foreboding; the pulse is quick, jerking, small, and sometimes wiry; the sleep is imperfect and disturbed by frightful dreams; the skin is hot, dry, and difficult of relaxation; the extremities are inclined to be cold; and there are frequently nervous rigors, followed by marked reaction and great restlessness; severe suffering is generally complained of in the loins and muscles; the slightest noise and light are annoying; and the head is distracted with severe pain, which often assumes a neuralgic character, and thus becomes a cause of great distress.

There are some low forms of inflammation in which the attendant fever nearly always assumes this peculiar type, being present almost from first to last. A good example of it is afforded in dissection-wounds, in certain injuries of the skull and brain, in phagedenic ulceration, in hospital gangrene, in sloughing chancres and buboes, in carbuncles, and in tertiary syphilis, in nervous debilitated subjects.

3. CHANGES OF THE BLOOD IN INFLAMMATION.

That the blood, which plays so important a part in the economy in health, should be seriously altered in inflammation, is what might naturally be anticipated, and what observation fully verifies. Sent with increased force and rapidity through every portion of the body, however constituted, or however remote from the heart; subjected to new actions and new affinities in the suffering structures, as if it were exposed to the heat of a laboratory, and deprived, in great degree, of the stimulus of the oxygen of the air, it is not surprising that it should be almost totally changed in its physical, chemical, and vital properties. The most important alterations which the fluid experiences relate to the fibrin and colorless globules, the quantity and number of which are always materially increased in every well-marked case of inflammation.

In healthy blood the proportion of fibrin to the entire mass is as 3 to 1000; in inflammation, on the contrary, it is generally very much increased, ranging from 6 to 8, from 8 to 9, and from 9 even to $10\frac{1}{2}$, according to the intensity of the disease and the general powers of the system. In what proportion the colorless globules are augmented in inflam-

mation is still an unsettled question; that their number is materially increased is sufficiently obvious, but whether the change, in this respect, is as great as in the fibrin is not ascertained. In addition to this increase in their number, there is a manifest increase of their bulk, as well as of their glutinous properties, thereby greatly promoting their tendency to cohesion to each other and to the sides of the vessels, which forms so striking a phenomenon in well-established inflammation.

This excess of fibrin and white globules is generally observable at an early period of the inflammation, and gradually increases until the morbid process has attained its maximum, when it begins to decline, and finally altogether disappears with the causes that induced it. Although it is most conspicuous in the higher grades of inflammation, there are few cases in which it is wholly absent, unless the disease is so slight as not to produce any serious structural changes, or material embarrassment in the force and rapidity of the circulation in the part and system. Gout and rheumatism, pleuritis, pericarditis, pneumonitis, hepatitis, splenitis, arteritis, and acute articular affections usually exhibit it in the most marked degree. It is also present, but less conspicuously, in inflammation of the skin, connective tissue, and mucous membranes. Where or how this change is produced is still a mooted question. It is probably mainly effected in the arteries and veins by the agitation which the blood experiences in its passage through the different parts of the body, its various ingredients being thus forcibly pressed and rubbed against each other, and against the sides of the vessels by the increased powers of the heart. A species of disintegration is thus established, which doubtless adds very greatly to the already existing excitement both of the part and system. The idea that attrition of the blood against the walls of the arteries is mainly instrumental in the production of the change in question derives additional support from what is observed when a horse is subjected to severe exercise upon the turf. If the animal be bled immediately after having been driven very rapidly, a great increase of fibrin and colorless globules will be found, evidently dependent upon the increased momentum of the circulation. Now this is precisely what occurs in inflammation; the greater the excitement of the heart or the more intense the morbid action, the greater will be the amount of fibrin and of white globules, and conversely.

The increase of fibrin and white globules in inflammation is attended with inordinate contraction of the crassamentum, and a separation of the red particles, leading to the formation of what is called the *buffy coat* of the blood. This consists of a whitish, bluish, or tallow-like pellicle upon the top of the crassamentum, which begins to show itself the moment the blood commences to coagulate, and attains its greatest height after the consolidation is completed. The thickness and density of the buffy coat are greatly influenced by internal and extrinsic circumstances, as the state of the system, the intensity of the disease, and the manner in which the blood is drawn. In some instances it is a mere delicate film, while in others it forms a firm layer several lines in depth. When the blood is much impoverished by protracted disease, long abstinence, or unwholesome food, the buffy coat is generally very thin, soft, turbid, and iridescent, forming a striking contrast with the characters exhibited in plethoric states of the system.

Of the various extraneous circumstances which influence the formation of the buffy coat, the most important, in a practical point of view, are the shape and capacity of the receiver, the size of the stream, and the motion to which the blood is subjected in its passage from the vein. It is most readily produced when the fluid falls into a deep, narrow vessel, from a large orifice, at the rate of two to three ounces in the minute. If the blood runs very slowly, or in a tiny stream, or if the stream, although quite bold, is received into a cold or shallow basin, the buffy coat will either not form at all, or so very imperfectly as to be scarcely appreciable. Sometimes the blood is merely sizy, the fibrin resting upon the top of the cruor like an imperfect bluish film.

The buffy coat essentially consists of plasma, blood-liquor, or fibrin, in combination with albumen and earthy salts. In fact, it is perfectly identical with the plastic matter that is poured in inflammation. By a little care it may easily be detached from the crassamentum; and, after being well washed in cold water and immersed in alcohol, it assumes not only the peculiar buff-colored aspect, whence it derives its name, but a very dense, firm consistence.

Of the manner in which the buffy coat is formed no very satisfactory explanation can be offered. It was formerly supposed to be owing to the more tardy coagulation of the blood, thereby permitting the red particles to disengage themselves from the fibrin and to sink, by their greater specific gravity, to the bottom of the crassamentum. But this was evidently a mistake; for it is now well ascertained that inflammatory blood, instead of solidifying more slowly than healthy blood, generally concretes very rapidly and firmly,

thus impeding instead of favoring the development of the buffy coat. The most plausible opinion perhaps is that the occurrence is due to the vital repulsion between the fibrin and red particles; or, what amounts essentially to the same thing, to the contraction of the former by which these little bodies are squeezed out of it, as water is squeezed out of a sponge, before the mass of the blood is fully coagulated. However this may be, it is impossible for the buffy coat to form unless there is a previous disunion of the principal constituents of the fluid, thereby establishing a predisposition to its occurrence. To ascertain whether this tendency to the development of the buffy coat exists, it is not necessary to employ a spoliative bleeding, but simply to draw a few drops of blood, and to look at it with the microscope, which will at once detect the slightest deviation from the normal standard. The red corpuscles will be observed to run almost immediately into clusters of piles or rouleaux, as represented in fig. 1.

In certain forms of inflammation and conditions of the system the blood is not only buffed, but cupped, the upper surface of the crassamentum exhibiting a hollow appearance,

Fig. 1.
Reticulated Arangement of the Corpuscles in Inflammatory Blood.

Fig. 2.
Buffy and Cupped Blood.

as if it had been scooped out with a knife. Such an occurrence usually denotes a higher degree of morbid action than the mere presence of naked fibrin on the top of the clot, and yet it is not unfrequently witnessed under circumstances which render it very questionable whether there is any inflammation at all, as in anemia, in scurvy, in chlorosis, and in profuse evacuations from the bowels, skin, and kidneys. To account for such anomalies, is generally not easy, but of their practical import every practitioner must be fully aware. In my private collection is a beautiful specimen, fig. 2, which I obtained by bleeding a young man laboring under pleuro-pneumonia, in which the buffed and cupped appearances coexist in a marked degree on both surfaces of the crassamentum.

It has not been ascertained what changes, if any, the red globules undergo in inflammation. That they are flattened and otherwise altered in their form is sufficiently obvious; and it is equally certain that they greatly diminish in number as well as in their coloring matter, during the progress of the morbid action, especially if at all severe or protracted, as is evinced by the pallor of the countenance and of the surface generally.

4. INTIMATE NATURE OF INFLAMMATION.

In the definition of inflammation, given in the early part of this chapter, no attempt was made to specify its true character or essential nature, as such a step would have been premature; but now that its various local phenomena have been pointed out and its constitutional effects traced, we are fully prepared to enter upon the subject, and to ask the question, What is inflammation?

To answer this question intelligibly, it is necessary to consider, 1st, the nature of the capillary vessels, in which the morbid action is mainly carried on; 2dly, the character of the blood, which, as already seen, is so singularly changed in this affection; 3dly, the part played by the nervous system, or, perhaps, more properly speaking, by the nerves of the affected structures; and 4thly, the condition of the tissues at the seat of the disease.

The capillaries are those minute canals which are everywhere interposed between the arteries and veins, and which are designed not merely as channels for the transmission of the blood, but also as organs for the elaboration of various kinds of fluids, as those of nutrition and secretion. In structure they differ from the arteries and veins only in the

fact that the finer ones consist of flat endothelial cells arranged in a tubular form, to which, in the larger, is superadded a tunic composed of a delicate network of fine fibrils, formed of the processes of the stellate cells which lie directly upon the vascular wall. With regard to their caliber, these vessels are divisible, for the sake of a more thorough comprehension of the subject, into two classes. The one embraces those minute tubules which, though invisible to the naked eye, carry a continuous stream of blood, so as to give the part in which they are situated, when examined with the microscope, a red appearance. The other group consists of vessels, the lumen of which is so small as to admit only a single globule at a time, and which it is often difficult to detect even with a strong magnifier.

Although the blood, as it circulates through the body, and immediately after it has been drawn from a vein of the arm, has the appearance of a homogeneous fluid, a careful examination shows it to consist of numerous elements, intended for widely different purposes in the economy. Coagulation separates it into two parts, one solid, and hence called the crassamentum; the other fluid, and called the serum. The crassamentum consists of a pale, whitish, transparent fluid, known as the blood-liquor, plastic matter, plasma, or coagulating lymph, and of minute particles, globules, or corpuscles, entangled in and suspended by it as the blood circulates through the body. The particles are of two kinds, the red and the colorless; the former, which impart to the crassamentum its red hue, are exceedingly abundant, and vary in size from the $\frac{1}{3000}$ to the $\frac{1}{3500}$ of an inch in diameter; they are of a flattened, biconcave, circular shape, and their office seems to be to absorb oxygen from the atmosphere and to convey it to the different parts of the system, to invigorate the organs and tissues. The colorless or white corpuscles—the leucocytes of certain authors—are much less numerous, but greatly multiply in inflammation; they are round, much larger than the red, and rough or finely granulated on the surface. What their precise office is is not determined, but it is certain that, at their expense, the red corpuscles can be regenerated; that they wander from the vessels into the surrounding tissues, where they proliferate; and that they play an important part in effecting certain plastic changes, if, indeed, they are not intimately concerned in the reproduction of impaired or lost structures.

In the vessels of the living body, the white globules have, apparently, no disposition to mingle with the red; on the contrary, they keep in close contact with the inner surface of the vessels, coasting, as it were, slowly along in the blood-liquor, outside of the general current. The red particles, on the other hand, pass quietly and gently along the centre of the vessels, regardless, so to speak, of the colorless, and in a much more rapid and lively manner, without any adhesion to each other, to the white particles, or to the coats of the containing vessels.

The essential elements of the inflammatory process, so far as we are able to comprehend them, are, 1st, slight contraction of the capillaries, with a retardation of the flow of blood; 2dly, dilatation of these vessels and an increased rapidity of the circulation; 3dly, exudation of blood-liquor, and emigration of white blood corpuscles; and, 4thly, a quiescent state of the capillaries, with complete stagnation of their contents. While these changes are going on in the interior of these vessels, important changes are wrought in the blood, both in regard to its consistence, its color, the arrangement of its globules, and the character of the plasma. Finally, the coats of the vessels themselves are seriously altered, being rendered abnormally soft and fragile, through fatty infiltration, and thereby temporarily incapacitated for the transmission of their contents. These various changes are so important as to demand separate consideration.

If a drop of rectified spirits, or of any mild stimulus, be applied to the web of the foot, the tongue, or mesentery of a frog, or the wing of a bat, the effect will be a slight contraction of the arteries, with a partial arrest of the flow of blood through the capillaries, the particles of blood moving to and fro for a few seconds, when they will be observed to regain their proper course, and to pass on as if nothing had occurred. If the irritation be more severe, as when a drop of tincture of capsicum is applied, the vessels, instead of diminishing, are instantly dilated, or if there be any contraction, it is so trivial and transient as to be inappreciable by the sight. However this may be, the dilatation soon becomes marked and decided, as is proved by the fact that the vessels now carry a much larger quantity of blood than naturally, the red particles being sent into them in increased numbers, as well as with increased force and velocity, evidently in consonance with the augmented action of the heart, which, beating perhaps from ninety to one hundred and ten in the minute, throws the fluid with extraordinary impetus into the inflamed part.

The disease advancing, the dilatation steadily augments, until, at length, the artery,

expanded to its utmost, is converted into a mere passive tube, palsied and crippled in its action, and therefore not only unfitted for transmitting its contents, but for performing any of its more delicate functions as an organ of nutrition and secretion. In other words, the rate of movement of the blood is again altered, primary acceleration giving way to retardation of the circulation.

In the condition now described, the capillary is not only greatly distended, but distinctly elongated and tortuous, sometimes almost knotty, as if affected with aneurismal enlargements, or veritable varices. Its coats are also abnormally soft and lacerable, from intermolecular changes in their structure.

The blood, the immediate cause of this dilatation, is literally impacted in the vessel, pressing everywhere upon its sides, and thus causing, by degrees, complete remora, stasis, or stagnation. The white and red particles, instead of pursuing an orderly, quiet, and independent course, as in the natural state, are now observed to be more or less intermixed, and so thoroughly crowded together that both are materially changed in their shape, being irregularly flattened, elongated, and distorted, as well as adherent to each other and to the sides of the vessel. When there is complete stoppage, the distinction between the two sets of globules is entirely lost, the blood forming a stagnant pool, of a dark homogeneous aspect.

These various changes, which are brought about gradually, not suddenly, may be studied with great advantage in what occurs in inflammation of the conjunctiva. If this membrane be irritated, as, for example, by the contact of a foreign body, there will be an immediate rush of blood to the part, with a great seeming increase of its vascularity. In a few minutes hundreds of vessels, previously invisible, will be seen shooting out in different directions, and connecting themselves with the sides of those that appeared in the first instance. These are not new channels, but old ones appertaining to the second class of capillaries, rendered evident by the intromission of red particles, which, in the healthy state, pass along so sparingly and in so slow and gradual a manner as to elude detection.

It is not to be supposed that the globules of the blood, as they are sent by the heart into the irritated arteries, are able, all at once, to pass through them without some difficulty. Instead of this, after having proceeded a certain distance, they rebound against themselves and against the sides of the vessels, so as to undergo a kind of oscillatory movement; but, gradually yielding to the force exerted upon them from behind, they are urged onward and onward until they reach the corresponding veins, into which, as their caliber is much larger than that of the arteries, they rush as into a vortex, and instantly disappear in the current beyond. A similar oscillatory movement of the globules of the blood is observed when the circulation is about to be reëstablished after it has been completely arrested. Some time is required for the detachment of these bodies, and when they have finally succeeded in effecting this, instead of passing on at once into the corresponding veins, they are propelled forward and backward until the diseased arteries are sufficiently dilated to admit of their escape.

When the morbid action is fully established, and at the same time very intense, without, however, there being as yet complete cessation of the circulation, the contents of the affected vessels not unfrequently break through their softened and lacerable walls, occasioning thus a veritable extravasation of blood.

Immediately around the seat of the greatest intensity of the morbid action, marked congestion exists, and the blood, consequently, passes along very slowly, and with difficulty. Beyond this point the phenomena are somewhat different; the excitement is less considerable, but still sufficient to cause active vascular determination; the blood moves in a continuous stream, and with extreme velocity, but being unable, as it approaches the focus of the inflammation, to make its way through the stagnant tubes, it is sent onward through collateral channels, now for the first time fairly opened for its reception. Thus it will be seen that, while at the centre of the morbid action stagnation occurs, and around this there is a sluggish circulation, an increased activity is going on in its neighborhood. The arteries leading to the affected part are distended, and pulsate strongly, but not with preternatural frequency.

The part played by the *nerves* in inflammation is very imperfectly understood. It is evident, however, that it is very important, although it is impossible to define its character or specify its degree. In traumatic inflammation, as well as in many cases of idiopathic, the vascular changes, which, as has been seen, consist essentially in dilatation of the vessels, with consequent diminution, retardation, and stasis of the circulation, cannot be referred to the blood itself, but must be seated in the vascular walls. Decrease of the resistance of the vessels to the pressure of the blood is probably due to perverted innerva-

tion.   The irritated sensory or nutrient nerves of the inflamed part impress the ganglionic centres in such a way that their action on the walls of the vessels through the vaso-motor nerves is diminished or inhibited, thereby producing lessened tone or reflex paralysis of their muscular fibres, as evinced by the dilatation of the vessels, and the consequent congestion of the tissues to which the irritated sensory nerves are distributed.   That the dilatation of the vessels and the hyperemia are not, however, necessarily of reflex origin, but that they may depend upon the direct influence of the irritating agent upon the walls of the vessels is demonstrated by the fact that they may be produced in the tongue of the frog after destruction of the nervous centres.

As the inflammation increases in intensity, the nerves actively participate in the morbid process, their substance becoming injected, softened, compressed, and otherwise altered, in consonance with the peculiarity of their structure and function.   The effect of such a change upon the welfare of the affected textures must be extremely pernicious, as it must materially diminish, if not entirely arrest, the nervous current, and thus weaken and prostrate their vital powers.

The joint agency of the nervous and vascular systems, in the production and maintenance of inflammation, has been happily illustrated by the researches of modern physiologists. Thus, for example, it has been ascertained, that, when the ophthalmic branch of the fifth pair of nerves is divided in the cranial cavity of a rabbit at the bridge of Varolius, inflammation is speedily lighted up in the surface of the eye, eventuating in opacity of the upper segment of the cornea.   What is still more remarkable is, that, when the nerve is cut on the petrous portion of the temporal bone, so as to involve the ganglion of Gasser, the resulting irritation is not only more violent, and much more deeply seated, but followed by complete disorganization of the organ.

Analogous effects ensue upon the division of the pneumogastric nerves.   When these cords are severed high up in the neck, the lining membrane of the air-passages assumes a dark color, the lungs are engorged with black blood, and an abundance of serosity is poured out into the parenchymatous texture, as well as into the pulmonary vesicles and the minute branches of the bronchiæ.   The pleura generally participates in the irritation, and there is almost always more or less inflammation of the stomach, with a suspension of the secretion of the gastric juice.

Animals in which the brachial plexus of nerves has been tied are soon seized with inflammation of the integuments of the remote parts of the limb, which gradually progresses until all the soft structures are invaded by gangrene.   A friend of mine removed a section of the peroneal nerve on account of a neuroma; the wound was long in healing, and two of the small toes sloughed before the patient recovered.   These facts enable us to explain certain circumstances that are noticeable in certain morbid states of the system.   A part, for instance, affected with palsy, is much less capable of withstanding the ordinary impressions of physical agents than one receiving its customary supply of nervous influence.   A burn in a paralytic person creates much more serious mischief than in a person in perfect health; and the same is true in regard to blisters and other irritants, the injudicious application of which often leads to the destruction of large portions of the skin and subjacent connective tissue.   There is little doubt that the inflammation of the bladder, which so frequently supervenes upon serious injury of the spinal marrow, is caused in a similar manner; that is, by the interruption of the natural supply of nervous fluid.

In whatever manner the parts are deprived of nervous fluid, it is presumable that they are brought under relations somewhat analogous to those of a frozen limb.   The temperature is lowered, the sensibility impaired, the process of nutrition perverted; in a word, the natural connection between the vessels and nerves is broken up, and hence that series of phenomena so characteristic of inflammation.

The saturation of the affected tissues with fluid exudation, through the escape of blood-liquor from the vessels, proceeds step by step with the diminution and retardation of the venous and capillary circulation, and forms one of the most essential characteristics of inflammation.   Although Bennett and Rokitansky had both been aware of the part played by the participation of the exudation of blood-liquor in the process of inflammation, it was not until recently that its importance in stimulating cell life, or modifying the healthy nutrition of local protoplasmic masses, was fully recognized.

Coincident with the exudation of blood-liquor and the other vascular changes above described, the white blood corpuscles, leucocytes, lymph corpuscles, nomadic or wandering cells, as these protoplasms are variously termed, greatly increase in number, and adhere to the inner surface of the vessels, forming upon it an almost motionless layer, while the red corpuscles circulate slowly along the centre in their accustomed channel.   Thus situ-

ated, the white corpuscles begin to wander out or emigrate into the inflamed tissues through the softened veins and capillaries, by virtue of the remarkable faculty which they possess of changing spontaneously their form and position, peculiarities which, from their similarity to those of amœbæ, are designated as amœboid movements. This faculty, as well as the diffusion of the white corpuscles in the tissues, was first demonstrated by Von Recklinghausen, without, however, his being aware of their vascular origin. Addison, in 1842, enunciated the fact that in inflammation the white corpuscles first pass into and then out of the walls of the vessels; and Waller, four years later, by experiments performed upon the tongue of the frog, confirmed the statements of his countryman. Although, subsequently, Stricker, of Vienna, discovered that the walls of the vessels are permeable both to the white and red corpuscles, it remained for Cohnheim, in 1867, to establish the correctness of these observations, by demonstrating conclusively that white blood corpuscles wander from the vessels into the irritated and inflamed tissues, and that, in incipient inflammation, all such morphological elements as cannot be distinguished from pus corpuscles, are derived from the blood, and not from the tissues. To Cohnheim, therefore, is due the credit of having correctly intrepreted his own observations, and of developing the researches of his predecessors. Having once infiltrated the inflamed tissues, these white corpuscles germinate, and become either fixed connective tissue cells, forming in conjunction with other tissue proliferation, the germ tissue of Rindfleisch, the granulation tissue of Virchow, or the plastic infiltration of certain pathologists; or, they are thrown off by the tissue in the form of pus; or, as observed by Hering, they may enter the lymphatic vessels, to be carried to distant points as lymph corpuscles; or, finally, they may reënter the veins and capillaries, as pointed out by Von Recklinghausen, the ultimate disposition of the protoplasm being determined by the intensity and duration of the morbid action, the texture or organ affected, and the state of the blood.

Not less important than the vascular changes in inflammation is the succeeding nutritive disturbance of the *cellular elements of the perivascular tissues*, due to the stimulating influence exerted upon them by the exuded blood-liquor, and manifesting itself by increase of substance, change of form, and proliferation, either through fission, germination, or endogenous generation. Proliferation, multiplication, or germination of local protoplasmic masses, accompanies inflammation of all organs and textures, in consequence of the assimilation by the germinal matter of an excess of new material derived from the blood-liquor. This activity of cell life has been observed in nearly all types of cells, both of non-vascular and vascular connective tissues. Thus, for example, the investigations already alluded to, of Stricker and of W. F. Norris, of this city, have demonstrated the proliferation of the germinal matter of the cornea corpuscles; Güterbock has shown the division of the nucleus of the cells of tendons; and Redfern, as is well known, first observed that the germinal matter of the normal cartilage cell is replaced by a mass of mobile cells, which are identical with white blood corpuscles. Similar hypernutrition of cell elements occurs in the vascular connective tissues. The researches of Stricker proved the increase by division of white blood corpuscles, and he has, moreover, confirmed the doctrine of Virchow that the fixed connective tissue corpuscles multiply in the same manner. Even in the capillary vessels, which are nothing more than tubular protoplasms, it has been ascertained by Beale, Stricker, Leidesdorf, and Shakespeare that similar growth and division take place; the former distinguished observer, moreover, believing, from the likeness of such dropped off bodies to white blood corpuscles, that they represent one of the modes of genesis of the latter. Finally, the participation of the muscle corpuscles in the process of inflammatory formations has been demonstrated by Virchow, Waldeyer, Weber, Weil, Spina, and Tschainski; and the nuclei of nerve cells, are said by Jolly, under certain circumstances, to increase in number.

Local disturbance of nutrition in inflammation is also indicated by the changes which occur in epithelial cells. Buhl and Remak discovered the endogenous proliferation of the germinal matter of the epithelial cells of suppurating mucous membranes; and the fission of the protoplasm of the epithelial cells of the corneal conjunctiva, and of the membrane of Descemet, has been observed respectively by Oser and Stricker. Analogous changes occur in the cells of the secreting glands, as is exemplified in those of the liver, which have been shown by Holm and Hüttenbrenner to participate in the formation of inflammatory products.

To what conclusions do these remarkable discoveries point? Simply, that the process of inflammation is attended with local disturbances of circulation and nutrition, the latter being dependent upon the former, which manifest themselves, first, by the escape through the walls of the thinned, softened, and dilated veins and capillaries of more blood-liquor than

is essential to normal nutritive changes ; and, secondly, under the influence of the assimila-
tion of an excess of new material derived from that fluid, by increased activity of the cel-
lular elements of the part, whether they be natural to it, or intruders from the bloodvessels,
as shown by their enormous multiplication.

The accumulation of young cells in the tissues thus gives rise to inflammatory new
formations, or plastic infiltration, which cannot be said, on the one hand, to be due exclu-
sively to the emigration and migration of white blood corpuscles, as advocated by
Cohnheim and his followers, or to be derived, on the other hand, exclusively from the con-
nective tissue corpuscles, as taught by Virchow and his school. On the contrary, both
elements participate in the process, as do the surface epithelia, gland cells, muscle corpus-
cles, nerve cells, and, in point of fact, all cells found in the tissue or organ affected. In
an irritated cornea, for example, it has been established beyond cavil that wandering cells
intrude into its substance and proliferate ; that the proper corneal cells germinate, and
that the epithelial cells of the anterior and posterior layers of that structure undergo simi-
lar changes. What is true of the cornea may be applied to other tissues, so that it may
be laid down as a general law that the inflammatory process is essentially characterized by
hypernutrition of the local masses of protoplasm influenced by it.

The migration theory of Cohnheim has recently been opposed by Stricker, who teaches
that the inflamed tissue returns to its embryonic condition by the conversion of its cells
and basis substance into an amœboid material, which subdivides into the small cells,
which are regarded by Cohnheim as emigrant white corpuscles, and by Virchow as multi-
plying connective tissue corpuscles. While I can see no objection to the acceptance of
the theory of the metamorphosis of the entire tissue into germinal or embryonic tissue, I
am not prepared to discard the view of the part taken by emigrant cells in plastic infiltra-
tion, which appears to me to have been settled beyond the possibility of refutation by the
observations of the most competent authorities.

Some of the changes which occur in the vessels and tissues in inflammation are admir-
ably depicted in fig. 3, for which I am indebted to Dr. E. O. Shakespeare, representing
the appearance of the mesentery of a rabbit in a state of acute inflammation of about
twenty-four hours' duration, as seen under a magnifying power of three hundred diameters,

Fig. 3.

Changes in the Bloodvessels and Tissues in Inflammation.

after the superficial endothelial covering has been removed. At the lower and right-hand
portion of the figure the elements and tissues are quite sharply defined, whilst in many
other places they are considerably out of focus. A portion of a network of capillaries, c,
crowded with numerous white corpuscles and a few red disks, and possessing swollen
nuclei, n, in its walls, which are somewhat too sharply delineated, occupies a level in the
thickness of the mesenteric tissue just beneath the endothelial covering. By focusing
slightly deeper, a layer becomes apparent, in which a small vein is discovered imme-
diately beneath a portion of the capillary network. Its axis is found crowded with
red blood corpuscles, a, whilst the inner surface of the wall, b, of the venule is covered
with closely-packed and adherent white corpuscles, g, several layers deep, among
which, scattered at rare intervals, are a few red blood disks. At k, and at similar
locations, swollen granular nuclei of the endothelial lining of the inner tunic, are plainly

visible, and it will be observed that analogous nuclei also cover the exterior surface of the wall of this minute vein. The venule is surrounded by a perivascular lymph space, *e*, which is filled with great numbers of leucocytes accompanied by a very few red disks. The wall of this space also is lined with endothelium, having one or more swollen granular nuclei, as seen at *i*. In one or two places leucocytes can be seen partly in and partly outside of the vein wall. The connective tissue, *d*, *f*, is in a condition of decided change. Many of the lymph spaces between the bundles of fibres are distended, as at *f*, with lymph rich in leucocytes, and the walls of these spaces can frequently be seen, as at *h*, to be lined with swollen granular endothelium.

Although Cohnheim demonstrated the identity of white blood corpuscles with those of pus, and showed that in acute inflammation pyogenesis was referrible principally to vascular origin, the fact must not be lost sight of that white blood corpuscles only are converted into pus corpuscles under certain circumstances. The question then naturally arises, what becomes of the inflammatory new formation—of the tissue infiltrated with crowds of young cells? Without entering into minute morphological details, it will be sufficient to say that, if the inflammation be slight, the cells disappear, partly by their conversion into connective tissue, partly by atrophy and disintegration, and partly by entering the lymphatics or bloodvessels. If the morbid process pass into solid plastic infiltration, the cells assume new forms, and are changed into fixed connective tissue corpuscles, while the gelatinous intercellular substance, or the original tissue, softened and swollen by exuded blood-liquor, is rendered more and more firm, until its final conversion into analogous tissue. If, on the other hand, the inflammation be more active, fluid inflammatory infiltration ensues, the cells proliferate and retain their form, the intercellular substance liquefies, and suppuration is said to exist. In what manner these different results are determined, why one tissue should recover rapidly and without suffering any visible signs of injury, while another is disorganized, are points which cannot be answered in the present state of our knowledge; but there is no doubt whatever that the process is a vital one, and that it is materially influenced by the intensity of the inflammation, by the nature of the affected structures, and by the condition of the blood.

A careful study of the inflammatory process leads to the conviction that, in its earlier stages, it is one of increased action, not only of the arteries, veins, and capillaries, but also of the tissues through which they pass. It may, therefore, be assumed that it has its seat in and around these vessels, no single factor being decisive, since the vascular and extravascular characteristics are so inseparably blended and interdependent that all must participate in its development. In summing up the essential elements of the process as they have here been described, it will be found that they consist, in the order of their succession, 1st, of irritation; 2d, of perverted innervation; 3d, of deranged circulation, as evinced, primarily by acceleration, consecutively by retardation, with the penetration of the vascular walls by blood-liquor and white blood corpuscles, and, finally, stasis; 4th, of textural or nutritive disturbances, due to hypernutrition of local protoplasms; and, 5th, of new formations.

If, when inflammation is in its incipiency, there is augmented action, it follows, as a natural consequence, that, when the disease is fully established, there must be corresponding debility. The capillaries are not only distended to their very utmost with non-oxygenated blood, but partially, if not completely, paralyzed; the tissues, at the seat of the disease, are surcharged with inflammatory products; all the normal functions are interrupted or suspended; and vitality itself is sadly impaired. At no long interval, the affected structures, especially if loaded with plastic deposits, evince a disposition to undergo the fatty degeneration, the earliest evidence of the occurrence being the confused appearance of the parts as revealed by the microscope, and by the presence of minute oil globules. If the fibrinous matter is spoiled, or transformed into pus, the quantity of oil greatly increases, and the tissues, acted upon by the absorbents and by chemical influences, are liquefied and devitalized. If, on the other hand, it becomes organized, the parts are in danger of being atrophied, as they are partially robbed of their nourishment, and choked as vegetables are choked by weeds.

Much discrepancy of opinion still exists among surgeons as to what constitutes inflammation; some, myself included in the list, believing that only a very slight degree of action is necessary, while others maintain that a very wide departure from the normal standard is essential. Some, indeed, assert that there is no inflammation, properly so called, unless there is suppuration, apparently losing sight of the fact that the disease very frequently proves fatal long before it has attained this crisis. Others, again, consider

fibrinous exudation an indispensable condition of the process.   As for myself, I am satisfied that it is not necessary that there should be even an effusion of plasma, or fibrinous exudation, much less suppuration, inasmuch as there are certain organs and tissues, in which, however violent the inflammation may have been, the most careful examination, microscopical and chemical, fails to detect after death the existence of fibrin in the affected structures.   It is only necessary to instance the arachnoid membrane, the aponeuroses, bones, cartilages, and nerves, in which this disease is frequently, if not generally, unattended by a deposit of plasma, especially in its milder forms, and in its earlier stages. The quantity of this substance, and the facility with which it is poured out, must necessarily be very materially influenced by the nature of the affected organs and tissues, some furnishing it much more readily, and in much greater abundance, than others.   Moreover, it requires very nice judgment, particularly in the living subject, to define the boundaries between congestion and inflammation, or to determine where the one terminates and the other begins.   Inflammation, in its incipiency, may be compared to a latent or smothered fire, kept in abeyance by a redundancy of surrounding material ; exudation cannot occur all at once ; some time is necessary to prepare the vessels for their new office : so it is with the flame in the furnace, it does not break forth immediately on the application of the kindling, and yet no one would thence conclude that fire was not actually present. Most of the disputes that has grown out of this question have arisen from a misunderstanding as to the amount of disease, or change in the affected part, that is necessary to constitute inflammation ; and it is obvious that there never can be any fixed or definite views upon the subject so long as this is the case ; nor can the question be satisfactorily settled, unless it be studied with reference to the nature and functions of the different organs and tissues of the body ; or, if the expression be allowable, the conduct and habits of the organs and tissues in their healthy and morbid relations.

Another source of difficulty, in the settlement of the question, is the fact that many practitioners are seemingly incapable of divesting themselves of the idea that inflammation must necessarily be treated by depletion, particularly by the lancet, leeches, purgatives, and starvation.   They find it apparently impossible to disconnect the two things, and yet it requires very little reflection, and certainly no great amount of experience, to show the erroneousness of such a conclusion.   Cases of inflammation are of daily occurrence which imperatively demand the use of stimulants from their very commencement ; and it is not going too far to assert that there is a period in almost every attack of the disease, in which, if it be at all severe, the patient will not be greatly benefited by the use of **brandy, wine, quinine, and nutritious food.**

Attempts have been made from time to time to invent theories of inflammation which should satisfactorily explain its character, the philosophers who have thus occupied themselves imagining that, with the aid of the microscope and other ingenious appliances, they could penetrate the very secrets of nature, by tracing out her most intricate and hidden operations, and the laws by which these operations are governed.   How futile all such attempts have been, and are likely to be, the history of the subject amply attests. Theory has succeeded theory, only to be ridiculed, and to work out, so to speak, its own fallacy and insufficiency.   The cautious observer contents himself with things as he discerns them, unbiassed by prejudice and conjecture, satisfied if he can occasionally pick up a pebble at the bottom of the great sea of knowledge.   Viewed in this light, and measured by this rule, the theories of one man are of no more importance than those of another ; as guides to clinical observation, and as aids to practice, they are utterly valueless.   It is fortunate for us in this matter-of-fact age that we are not obliged, as was the case in former times, in order to establish our claims as philosophers, to speculate about **the final causes of things.**

5. TREATMENT OF INFLAMMATION.

There are two leading indications in every case of inflammation when sufficiently grave to demand interference, the first being the removal of the exciting cause of the disease, and the second, the establishment of resolution.

In regard to the first of these points, it is obvious that, although the disease may be modified in its character, or rendered comparatively harmless, by treatment, yet it will be impossible to arrest it completely so long as the exciting cause is operative.   Thus, for example, in strangulation of the bowel, it would be folly to expect resolution of the inflammation so long as the strangulation which has produced it continues.   In such a case, one of two things must necessarily happen : either the sufferer must die from the effects of the disease, or he must be relieved by the knife, or by nature's operation, the

formation of an artificial anus. An inflammation of the lungs from the presence of a foreign body in the air-passages cannot be effectually cured so long as the foreign body remains, and keeps up the morbid action. A similar remark applies to inflammation of the bladder from hypertrophy of the prostate gland. The gland, acting obstructingly to the flow of urine, is the cause of the cystitis, and just so long as the enlargement remains will the disease continue, although, as stated above, it may be materially modified by therapeutic measures. But it does not follow, on the other hand, that the inflammation shall at once subside because the exciting cause has been removed. The malady may already have made such decided progress as to render the restoration of the part either impracticable, or possible only after a long time and after much suffering. In our attempts to get rid of the exciting cause by mechanical means, it is hardly possible to exercise too much care and gentleness, or to institute them too early. All officious interference, rude probing, or rough manipulation, must be avoided, lest we add, as it were, fuel to the flame, aggravating and perpetuating the disease. Splinters, nails, needles, pieces of bone, are extracted with the finger and forceps; the calculus is cut out of the bladder; the speck of steel is picked from the cornea; the aching tooth is lifted from its socket; all in as gentle and easy a manner as possible.

It is not always, however, that the exciting cause of the malady can be detected, however carefully or assiduously it may be searched for. Very frequently, indeed, the cause is latent, the morbid action having, to use a very common but unphilosophical expression, sprung up spontaneously. Such an occurrence is, of course, impossible; there must necessarily be a cause for every disease, although it may not be in our power to discover it; hence, to wait for its removal before we begin the treatment, might sadly endanger both part and patient.

The second indication is to establish resolution or to disperse the morbid action, with the least possible detriment to the structures and functions of the diseased parts. To effect this, various remedies may be necessary, some being addressed to the general system, others directly to the affected parts; circumstances which have given rise to the division of the treatment of inflammation into constitutional and local, or general and topical.

I. CONSTITUTIONAL TREATMENT.—The constitutional treatment of inflammation consists of bloodletting, cathartics, emetics, depressants, mercurials, diaphoretics, diuretics, anodynes, tonics, and antiperiodics, with the addition of what is known as the antiphlogistic regimen. It is not to be supposed, however, that all these means, or even a majority of them, are necessary in every case of this disease; so far from this being true, the morbid action often disappears spontaneously, or under the mildest and simplest remedies. Whenever constitutional treatment is demanded, it should be employed as early as possible, and with a determined hand, with the hope of arresting the inflammation before it has made any serious inroads upon the part and system. A few doses of medicine, judiciously administered at the outbreak of the disease, often do more good than twenty administered after it has attained its full development.

In speaking, as I shall have frequent occasion to do in the following pages, of the "antiphlogistic" treatment, I shall employ this expression, sanctioned by long usage, wholly in a conventional sense, and not in that of the older pathologists. An antiphlogistic remedy may, in the modern acceptation of the term, and in the sense in which I shall here use it, be mild or harsh, gentle or heroic, soothing or perturbating, according to the exigencies of each particular case of inflammation, injury, or disease. To treat all patients similarly, or on one uniform plan, would simply be absurd.

1. *Bleeding.*—General bleeding may justly be regarded as standing at the very head of the list of the constitutional remedies for inflammation, as it is at once the most speedy and the most efficient means of relief. The blood is usually drawn from one of the larger veins, and is permitted to flow until a decided impression has been made upon the system. When we consider the singular changes which this fluid undergoes in inflammation, the fact that it is sent in an unusually large quantity to the affected parts, and the circumstance that it is mainly instrumental in supporting the powers of the heart, it will not be difficult to form a correct idea of the importance of this operation, or of the influence which it exerts in combating morbid action. Its value was not overestimated by the older writers when they designated it as the "great remedy" in the treatment of inflammation; yet, strange to say, bloodletting, notwithstanding the high rank which it formerly occupied, as an antiphlogistic agent, has, of late, fallen very much into disrepute, not only in Europe, but on this side of the Atlantic, where it had at one time so many advo-

cates. A great change has come over the profession in this respect, within the last thirty years, a change which has so completely subverted all our preconceived notions upon the subject, as to render it very questionable, in the opinion of many, whether blood-letting is really ever required as an antiphlogistic. To what is this change due? Is it justly attributable, as has been asserted, to a modification of the type of disease, and to a gradual diminution of the strength of the American people? If it be, I have not been able to discover it. On the contrary, I am perfectly satisfied that inflammation possesses the same characteristics now that it did formerly, and it is equally clear to my mind that patients bear depletory remedies quite as well now as they did then. The change has been the result of the natural progress of events; of a more thorough and enlightened knowledge of pathology, diagnosis, and therapeutics; and, in some degree, of the pernicious influence which a few prominent and distinguished teachers have exerted upon the professional mind. Authority never fails to find followers, so much easier is it to be led than to think. The result is that bleeding is no longer fashionable; it is denounced by nearly every one. For myself, I cannot but regret this change, for it requires no argument to show its fallacy. If formerly we bled too much, too frequently, too copiously, and too indiscriminately, it is equally certain that the operation is not employed often enough at the present day. Many a deformed limb, blind eye, enlarged spleen, and crippled lung bear testimony, in every community, to the truth of this remark.

General bleeding is employed with different views. In the first place, it diminishes plethora and reduces the temperature of the body; secondly, it changes the qualities of the blood, and thus renders that fluid more healthy; thirdly, it weakens the powers of the heart and nervous system, and, consequently, the momentum of the circulation; and, lastly, it promotes the action of other remedies.

To obtain these effects in the most speedy and thorough manner, the blood should be taken from a large orifice in a large vein, the fluid running in a bold, full stream to the amount of at least three ounces in the minute, the patient being either in a sitting or standing posture at the time. If the operation be performed during recumbency, a much larger quantity will be required to be drawn before the part and system become sensible of the loss. When the object of the bleeding is merely spoliative, or intended to rob the vessels of an unusual amount of their contents, it may be done in this way; but even then the better plan will be to bleed in the semierect posture, reopening the vein a second and even a third time, if premature syncope interfere with the requisite abstraction. The difference in the effect of these two methods of bleeding is forcibly exemplified in conjunctivitis. A patient who is bled in the erect posture soon begins to feel faint, and to experience relief from pain, the eye at the same time exhibiting a blanched appearance, instead of the scarlet hue which it had a moment before; whereas one who is bled in the recumbent posture will retain his strength for a much longer time, and when, at length, he is rendered unconscious, the inflamed surface will be found to be still comparatively red. The impression, moreover, will generally be much more permanent in the former than in the latter, and the return, consequently, of the capillary injection more slow and less perfect.

The circumstances which call for this operation are, generally speaking, a hard, strong, full, and frequent pulse, a plethoric state of the system, and great intensity of morbid action. When such a conjunction exists, the surgeon cannot possibly go amiss in regard to the abstraction of blood, constitutionally considered. He may, perhaps, it is true, combat the disease without such recourse; by the use of antimony, purgatives, and other means, he may gradually bring down inordinate excitement, and thus afford the affected structures an opportunity of throwing off the burden with which they are oppressed; but if he wishes to make a prompt and decided impression, spoliative and depressive, upon the part and system, he can accomplish his object much more readily and effectually with the lancet than with any other remedy in the whole catalogue of antiphlogistics. If nauseants depress the heart's action equally with the lancet, they certainly do not produce the same effect in unloading the engorged capillaries at the seat of the inflammation, in restoring the circulation, and in reclaiming morbid structure. The operation of the one is gradual, and, at times, almost imperceptible; of the other, prompt and decisive, often cutting down the disease with a single blow; or, at all events, leaving it in a condition to be afterwards easily dealt with by other and more simple means.

When bleeding is required, the earlier it is performed the better. Ten ounces of blood taken at the beginning of an attack of inflammation will usually do more good than four times that quantity drawn after the disease is firmly rooted. Indeed, when a part is once overburdened with deposits, the salutary period for general bleeding may be

considered as being passed; for, although the operation may aid in reducing the force of the heart, in lessening temperature, and in promoting the action of other remedies, it certainly does not exercise the same happy influence upon the capillary vessels at the seat of the disease.

The quantity of blood drawn at a single operation may vary according to circumstances, the object being effect, and not ounces; for what would be a large bleeding for one person might be a small one for another. From sixteen to twenty ounces is a good average loss. Some individuals faint almost as soon as the blood begins to flow, while others can scarcely be made to faint, no matter how they are bled, or how much blood is drawn. The best plan, therefore, always is to continue the operation until it has made a decided impression both upon the nervous and vascular systems, avoiding actual syncope, but inviting an approach to it, and then guarding against the danger of excessive reaction.

In former times enormous quantities of blood were occasionally removed for the cure of inflammation. The memoirs of the French Academy furnish instances of the abstraction of three hundred ounces within a week; and equally astonishing examples have been recorded by British writers. The late Dr. John W. Francis, of New York, while laboring under a violent attack of croup and tonsillitis, was bled to the extent of nearly two gallons and a half in a few days. Such cases are remarkable as showing the wonderful power of endurance of the system, but are not to be held up as examples for the imitation of the modern practitioner. It must be understood, however, that inflammation often engenders a tolerance of bleeding. Thus, a nervous person who in the healthy state will faint from the loss of a few ounces of blood, will, when laboring under severe inflammation, bear with impunity the loss of perhaps ten times that amount. A similar tolerance of remedies is frequently established by disease. In delirium tremens, opium may be given in doses that would destroy half a dozen healthy persons; in pneumonitis, the stomach acquires an extraordinary degree of tolerance for tartar emetic; and in croup, iritis, synovitis, and in certain forms of syphilis, mercury may be given in large quantities without salivation, the system being seemingly insusceptible of its influence.

The first effect of a loss of blood upon the system is a sense of muscular debility. Presently, the individual begins to look pale, to see indistinctly, to be confused, to hear unnatural noises, and to feel light and giddy. If the flow be not immediately stopped, he will next become deadly sick at the stomach, convulsive tremors will pervade his limbs, the pallor of the countenance will increase to a deadly white, the respiration and pulse will nearly cease, and, if he is not supported, he will fall down in a state of unconsciousness. He has fainted. Such an effect is sometimes produced by the loss of a few drachms of blood; at other times not until many ounces have been drawn.

Syncope must be relieved gradually, not too suddenly, lest there should be undue reaction, by recumbency, by loosing the patient's clothes, by dashing cold water upon the face, or face and chest, and by a free access of air, obtained by throwing open the doors and windows of the apartment, aided, if necessary, by the fan. If consciousness do not soon return, the body is raised a little higher than the head, ammonia is rapidly passed to and fro under the nose, and sinapisms are applied to the extremities and the precordial region. Sometimes a draught of cold water will do more in reviving the patient than anything else. If, from idiosyncrasy or excessive loss of blood, the syncope assumes an alarming character, a stimulating enema is administered, and mustard is applied to the spine and chest, or, what is far more efficacious, the patient is suspended by his legs; but nothing is given by the mouth, unless it is certain that there is still some power of deglutition.

The immediate cause of syncope is an imperfect supply of blood in the brain, and the object in placing the patient, while in this condition, in the recumbent posture, is to enable the enfeebled heart to force the vital fluid more readily and freely into that organ. The reaction succeeding the stage of depression is characterized by a gradual return of the various functions of the body to their natural condition. The color reappears upon the cheeks, the heart and lungs act more energetically, the limbs regain their warmth, the surface often becomes slightly moist, and the mind recovers from its confusion. The only treatment necessary, during this stage, is proper vigilance, lest the reaction should become too vigorous; depression being rather favored, when the morbid action is at all severe, than rapidly relieved.

When the loss of blood has been disproportionally great to the powers of the system, the stage of depression may be succeeded by dissolution, or reaction may at length occur, the struggle for many hours, being, perhaps, one of life and death. This state may be induced

by one copious bleeding, or by several small ones, establishing an undue strain upon the vital current. It is characterized by unusual pallor of the countenance, feeble pulse and respiration, coldness of the extremities, clammy perspiration, frequent moaning or sighing, great thirst and restlessness, vigilance, and a tendency to delirium. While the system is in this condition, local congestion, followed by inflammation, is not uncommon, the structures most prone to suffer being the brain, the arachnoid membrane, and the lungs. Sometimes the symptoms here described are mixed up with those of feeble reaction; and then the countenance, perhaps, is flushed, the eye and ear are intolerant of light and noise, the respiration is quickened, the skin is hot and dry, and the pulse is thready, hard, and frequent. The proper treatment does not vary essentially in the two cases, our main reliance being upon opiates in full doses, milk punch, quinine, and the bromides, with elevation of the head and cold applications, exclusion of light and noise, and blisters, if there be marked tendency to local determination. Further bleeding would only cause further sinking.

In the abstraction of blood various circumstances are to be taken into consideration, of which the most important are the age, temperament, and habits of the patient, the character and progress of the disease, the structure and functions of the affected organ, and the peculiar constitution of the atmosphere. Young and robust individuals generally bear bleeding much better than children and aged persons, who often experience great exhaustion from the loss even of a few ounces. Old subjects, in particular, are prone to suffer in this way, the system being often a long time in reacting, while in not a few instances the operation is followed by sinking. Infants and children are also slow in recovering from the effects of bleeding; but reaction having taken place, there is much less danger of ultimate exhaustion. Persons of a nervous temperament are less tolerant of the loss of blood than the sanguine and bilious. Corpulent persons are bad subjects for the lancet, and the habitually intemperate are liable to be thrown into delirium tremens by it. The inhabitants of densely crowded cities do not bear the loss of blood nearly so well as the residents of the country. During the prevalence of epidemics, as erysipelas, scarlatina, diphtheria, smallpox, measles, and puerperal fever, bleeding in any form is generally inadmissible. Finally, the abstraction of blood must be practised with the greatest circumspection in all cases of inflammation likely to be at all protracted, and in all persons suffering under grave accidents, as fractures, dislocations, and lacerated wounds, attended with danger of excessive drainage and hectic irritation. After severe operations and injuries, excessive loss of blood may seriously interfere with the restorative principle.

The more violent the inflammation is, the more reason will there be, other things being equal, for early and active bleeding; so also if the organ affected be one highly essential to life. Blood is seldom taken when the inflammation is inconsequential as it respects its degree and seat, milder means generally sufficing for its subjugation.

In regard to the repetition of the bleeding, the practitioner must be governed, first, by the intensity and persistence of the morbid action; secondly, by the importance of the organ attacked; and, lastly, by the state of the blood. The disease continuing with little or no mitigation, there will be the same reason for bleeding as in the first instance, and the last may now, perhaps, be borne much better, the previous abstraction having, it may be, engendered a certain degree of tolerance. Intensity of action will be an additional reason for the act. The importance of the organ attacked must not be overlooked. An inflamed lung requires more energetic measures than an inflamed skin, and an inflamed skin than an inflamed finger. As it respects the buffy coat of the blood, its value as a sign of the necessity of a repetition of the operation has already been pointed out, and need not, therefore, be again discussed. Associated with a persistence of diseased action, and a vigorous state of the circulation along with unusual firmness of the buffy coat, it is of some practical importance, but much less than was at one time supposed.

In considering the expediency of repeating this operation in old, decrepit subjects, the action of the heart, as ascertained by the hand and ear applied to the chest, will generally be a safer guide than the pulse at the wrist, which, from the force with which the blood is impelled into the radial artery, often imparts to the finger a deceptive sense of hardness, fullness, and vigor wholly incompatible with the actual condition of the vital powers at that period of life.

It is a matter of great moment, practically speaking, that the use of the lancet is not at all incompatible, in the treatment of inflammation, with the employment of beef-tea, beef-essence, milk punch, and other concentrated articles of food and drink. On the contrary, there is every reason why, in violent attacks of disease, they should go hand in hand, or contemporaneously and successively, the lancet relieving the affected structures deluged

with blood, while the nutrients supply the necessary pabulum for the support of the system, and the promotion of repair during the struggle between life and death. The exhausting effects of a copious bleeding, performed early in the disease, in a strong, robust person, before any serious injury has been sustained by the affected structures, are generally easily and rapidly recovered from, very much as when a strong, robust, healthy person is bled. The globulin which, under such circumstances, suffers more than any of the other constituents of the blood, is then speedily reproduced under the influence of a well-regulated diet and other restoratives.

2. *Cathartics.*—Cathartics constitute a most important class of remedies in the treatment of inflammation, being even more valuable than bleeding, because of their almost universal applicability. Their exhibition, however, should always be premised by the abstraction of blood, provided the nature of the case is such as to admit of it. When this is contraindicated, they may be given at once, and there are few surgical affections in which they will not prove eminently beneficial. Cathartics are usually divided into purgatives and laxatives, which differ from each other merely in the one being more active than the other. The distinction, however, is not without practical importance.

Cathartics, considered as antiphlogistic agents, are employed for different purposes. In the first place, they may be administered simply to evacuate the bowels; secondly, to deplete the mucous membrane, and thus diminish the quantity of blood in the system; thirdly, to excite the action of the liver, salivary glands, and mucous follicles; fourthly, to produce a revulsive effect, or to set up a new irritation at a distance from the original one; and, finally, to stimulate the absorbents, thereby inducing them to remove inflammatory deposits.

The importance of using cathartics as mere evacuants cannot be too strongly insisted upon when it is considered that an overloaded state of the bowels is one of the most fertile sources of disease. Many of the so-called idiopathic inflammations evidently owe their origin to this cause, as is proved by the fact that a dose of active purgative medicine often promptly removes them, especially if administered at the commencement of the attack. An incipient ophthalmitis, tonsillitis, or fever, is frequently cut short in a few hours simply by clearing out the bowels, and thus ridding them of irritating fecal matter and vitiated secretions. Besides, so long as the bowels are constipated, it is impossible for other remedies to produce their specific effect, or for the various secretions to recover their natural tone.

Secondly, this class of remedies proves useful in depleting the bowels, by abstracting the serous portions of the blood from the vessels of the mucous membrane, and thereby diminishing the quantity of fluid in the general system. This practice is often beneficially adopted in inflammation of the large intestine, as in diarrhœa and dysentery, and in the milder forms of inflammation in various parts of the body, where the loss of the red particles of the blood is of questionable propriety. An ounce of Rochelle salt, or half a pint of citrate of magnesium, will often carry away from eight to twelve ounces of serum from the bowels in a few hours, with the greatest advantage as it respects the morbid action.

Thirdly, cathartics may be given with a view of stimulating the liver, pancreas, and mucous follicles of the bowels. There are few inflammations, or diseases of any kind, in which disorder of the liver does not play a conspicuous part, either in exciting or maintaining morbid action. The quantity of fluid poured out by this organ, in health, in the twenty-four hours, probably amounts to nearly forty ounces, and it is, therefore, not difficult to form a tolerably correct idea of the ill effects that must result from the interruption, modification, or complete suspension of its functions. The irritating material which it is destined to eliminate being retained in the blood, there must arise, as a necessary consequence, serious derangement of the nervous and vascular systems, as denoted by the excessive lassitude, headache, excited pulse, and other symptoms, so conspicuous in disordered states of the liver. But a diminished supply of bile is not the only difficulty: on the contrary, the fluid may be secreted in unnatural quantity, and yet, if vitiated in quality, the effects will hardly be less serious. The pancreas, too, may have its functions deranged, which the well-directed cathartic may readily restore to their normal condition. Of the vast influence exercised upon the health by the mucous follicles of the alimentary canal, it is hardly possible to form any adequate conception. Existing, as they do, everywhere in vast numbers upon the mucous surface, the suppression of their functions, even for a short time, cannot fail to be followed by local inflammation in different parts of the body, or the material aggravation of it, if already lighted up. Hence, remedies calculated to restore, modify, or improve the secretions of these several structures constitute important objects of treatment, not only as preventives, but as means of cure.

Fourthly, the administration of cathartics proves useful on the principle of revulsion, metastasis, or counter-irritation, by establishing a new action in a part more or less remote from that originally affected. During the operation of a brisk purgative, as well as for some time after, there is an unnatural afflux of blood to the alimentary canal, by which the suffering organ is temporarily relieved of vascular turgescence, on the principle that two morbid processes cannot go on, to any extent, at the same time. This operation may be intermittent or permanent, according to the character of the cathartic and the mode in which it is exhibited. In inflammation of the head, throat, eyes, and, in fact, of the supradiaphragmatic portions of the body generally, this principle is never, for a moment, lost sight of by the practitioner, inasmuch as it constitutes a most important element of treatment.

Finally, cathartics, by clearing out the alimentary canal, and restoring the secretions, pave the way for the more successful action of other remedies, as diaphoretics, anodynes, diuretics, and sorbefacients. They exert, in this respect, very much the same influence, only in a slighter degree, as venesection and leeching, diminishing the volume of the circulating mass, and diverting the blood from the suffering organ. Relieving obstruction, restoring secretion, and establishing new action, they enable the absorbent vessels to recover from their torpor, and to render themselves useful in removing inflammatory deposits.

Cathartics are particularly valuable in inflammation of the brain and its membranes, the eye and ear, throat, respiratory organs, liver, skin, and joints. In gastritis, enteritis, peritonitis, cystitis, wounds of the intestines, and strangulated hernia, they are either contraindicated, or exhibited with the greatest possible circumspection, and only in the mildest forms. In most, if not in all, of these affections, the best purgative is the lancet, aided by large anodynes, either alone or in union with calomel. Tranquillity, not perturbation, is what is sought, on the principle that whatever excites peristaltic action must prove prejudicial to the inflamed surface.

Cathartic medicines must not be exhibited merely with a view of correcting disordered alvine evacuation. Such a procedure could not fail to prove injurious. The action of these remedies is perturbating, and therefore subversive of healthy function; hence, it would be unreasonable to expect that the discharges should be entirely natural so long as they are exhibited. The more frequently they are administered the more likely will this be the case.

When these medicines act tardily, their operation may be aided by injections; and cases occasionally occur where the latter remedies may advantageously, if not entirely, take the place of the former.

The number of purgatives and laxatives is very great, and the surgeon may therefore give himself considerable latitude in the choice of his articles. A few, however, either alone, or judiciously combined, will answer his purpose in nearly every case. When a merely evacuant effect is desired, nothing is better than a dose of castor oil, rhubarb, or jalap; the saline cathartics produce watery passages; calomel, blue mass, and gray powder act specifically upon the liver; and when an irritating, revulsive, or metastatic effect is wished, the proper articles are compound extract of colocynth, scammony, gamboge, aloes, and podophyllin. In external inflammations, as well as in inflammations of the supradiaphragmatic organs generally, one of the most useful cathartics, as I have found from long experience, is an infusion of senna, or of senna and Epsom salt. It operates not only promptly and powerfully upon the bowels, but also upon the liver, stimulating this organ to increased action, in a manner hardly inferior to calomel and blue mass. The only objection to its exhibition is that it is apt to gripe, but this tendency may usually be effectually counteracted by combining with it some carminative. Leptandra is also a good cholagogue, without so decided a purgative effect as pertains to calomel and senna, but this may be increased to any desirable extent by the addition of rhubarb, jalap, or podophyllin. Rochelle salt is at once an agreeable, cooling, and efficient laxative. Croton oil is rarely used, except to relieve obstinate constipation, and then only with the greatest caution.

Injections, clysters, or enemas, may be prepared of various articles, as gruel and common salt, water and mustard, castor oil, spirit of turpentine, infusion of senna, jalap, and other substances, according to the intended effect. An excellent enema, prompt and efficient in its action, may be made of one quart of soapsuds and two ounces of vinegar. Whatever material be used, the important rule is to mix with it a sufficient quantity of fluid, warm or cold, to distend the lower bowel. It may be administered with a hard rubber or a common pewter syringe, having a long nozzle, and capable of holding at

least from sixteen to twenty ounces; or, when there is obstinate constipation, with an ordinary stomach tube. The patient should lie upon his side or belly during the introduction of the instrument, and care taken that he be properly held, especially if he be delirious or otherwise unmanageable. A number of cases of perforation of the rectum caused by the reckless use of the syringe are upon record.

3. *Mercury.*—The reputation of mercury, as an antiphlogistic, has long been established. Although the precise mode of its action is still imperfectly known, its beneficial effects are well understood. Its virtue in controlling inflammation is hardly inferior to that of the lancet and of tartar emetic, while, during the decline of the disease, as a powerful sorbefacient, or promoter of the removal of morbid deposits, it is without a rival in the materia medica. It may, therefore, be given during the height of the malady with a view of arresting its progress, and subsequently, after this object has been accomplished, for the purpose of getting rid of effused fluids, or reclaiming oppressed and disorganized structure. The efficacy of the remedy, in both these relations, is particularly conspicuous in the phlegmasias of the fibrous and fibro-serous tissues, in gout and rheumatism, synovitis, carditis, arteritis, hepatitis, splenitis, pneumonitis, laryngitis, iritis, orchitis, osteitis, and in syphilis. It is less apparent, although not without its value, in inflammation of the brain, the skin, and mucous membranes, bronchitis, nephritis, cystitis, and metritis.

It is rarely that the treatment of inflammation is commenced with the use of mercury. It is only in very urgent or neglected cases that this rule is departed from, the potency and activity of the remedy being always augmented by previous depletion. Whenever, therefore, there is evidence of plethora, bleeding and purgation should precede its use. There is, so to speak, a mercurial point in inflammatory affections, prior to which the employment of this remedy either proves positively injurious, or greatly disappoints expectation. This point is characterized by softness of the pulse, a relaxed condition of the skin, moisture of the tongue, and a general tendency to restoration of the secretions. Administered during the height of the morbid action, when the whole system is enveloped, as it were, in flame, it can hardly fail to act as an irritant, and to increase the general excitement. For want of attention to this rule, a great deal of mischief is often done, and a remedy, otherwise of inestimable value, permitted to fall into disrepute.

Of the manner in which mercury acts in relieving inflammation, there is, as already intimated, no very definite information. That it affords powerful aid in controlling the action of the heart and vessels, both large and capillary, is unquestionable; but how this effect is produced, whether by any direct sedative impression it may exert, or by merely correcting the secretions, is still a mooted point. Nor is there any positive information in regard to the changes which mercury induces in the state of the blood. It is well known how greatly the properties of this fluid are modified by inflammation, what increase there is of fibrin and white globules, and how promptly, in many cases, these changes are corrected by the judicious use of mercury; but in what manner this is effected is, in the present state of the science, altogether inexplicable.

When the exhibition of mercury is pushed to the extent of active ptyalism, speedy changes are induced both in the solids and fluids. The patient soon becomes thin, haggard, and enfeebled, and the blood is rapidly changed in its properties, the fibrin being diminished, approximately, by one-third of its amount, the globulin by one-sixth, and the albumen by one-seventh, at the same time that it is surcharged with heterogeneous and irritating matter, the product of decomposition.

During the decline of inflammation, and, indeed, in many cases long after the morbid action has been completely checked, the judicious use of mercury is of the greatest advantage in effecting riddance of the morbid products. Of the manner in which this is done, direct ocular demonstration is occasionally afforded in some of the external phlegmasias. Thus, in iritis, if the system be placed under the influence of mercury, the effects of the remedy are rendered obvious by the daily progress which the affected structures make in freeing themselves of the plastic matter that was effused during the height of the inflammation, and which frequently proves so destructive to them by the changes which it induces in the pupil. Similar effects are witnessed in inflammation of the cornea, attended with interstitial deposits. The opacities which result from these deposits often vanish in a short time under the influence of slight ptyalism, the effect being frequently apparent before the action of the medicine is fairly developed. In orchitis, after the disease has measurably subsided, the swelling and induration are, in general, promptly dispersed under the use of mercurials, aided by rest, light diet, and purgatives. In all these, and similar cases, the beneficial effects of the agent are evidently due to its sorbefacient properties, or to the

manner in which it stimulates the absorbent vessels, compelling them to remove the products left by the previous action.

Administered merely as a sorbefacient, the effects of this remedy are often insensible, its action being exerted in a very slow and gradual manner, yet hardly any the less efficiently. This kind of action is particularly desirable in chronic diseases, attended with a crippled condition of the tissues from semiorganized deposits, and an enfeebled state of the general system. Under such circumstances, active mercurialization is altogether inadmissible, from its irritating and prostrating effects; while a more gentle and persistent course is often followed by the greatest benefit, the gums being merely touched, or rendered slightly red, tumid, and tender, as an evidence of the silent operation of the remedy.

The best form of exhibition of the remedy is calomel, blue mass, or mercury with chalk. When a prompt and powerful impression is desired, as when there is high inflammatory action, likely to prove speedily overwhelming in its effects, not only threatening structure but life, the medicine should be given in large and frequently repeated doses, so as to keep up a decided and well-sustained influence. For this purpose the best article is calomel, in does of three to five grains, administered every three, six, or eight hours, until we have attained the object of its exhibition. When the case is at all urgent, as, for example, in croup, pneumonitis, or carditis, no time is to be lost; whatever is done must be done quickly, with a bold, vigorous hand; the remedy must be given in full, not in small, insufficient quantities, or in a faltering, hesitating manner. There is but a short step between the disease and the grave, the struggle is one of life and death, and the victory must be accomplished, if accomplished at all, at all hazard, present or future. When the disease is less violent, or the organ involved less important to life, the medicine is exhibited in smaller doses, and at longer intervals, and then, too, instead of calomel, the milder forms may be used, as blue mass, or gray powder. When a chronic or insensible impression is desired, the bichloride may be given instead of calomel or blue mass, or the latter may be employed in smaller doses. Other forms of mercury, to be mentioned hereafter, as the iodide, and cyanide, are often beneficially prescribed in chronic diseases of the skin, in glandular enlargements, in chronic affections of the joints, and in tertiary syphilis. Mercury with chalk, or gray powder, is a great favorite with some practitioners in inflammatory diseases of children and aged persons; but I rarely use it, having frequently found it to nauseate and to be unworthy of reliance.

To prevent the mercurial from running off by the bowels, it is usually necessary to combine it with a certain quantity of opium, as a fourth of a grain, half a grain, or even more, with each dose, according to the particular exigencies. In children, and in all cases affecting the brain, opium should be given with great caution, especially during the violence of the morbid action. When the skin is hot and dry, the mercurial should either be entirely withheld until further depletion has been practised, or it should be united with some diaphoretic, as tartar emetic, ipecacuanha, or Dover's powder. Griping, which is so liable to occur during the progress of the treatment, should be counteracted by carminatives and laxatives, as oil, salts, or magnesia.

The administration of so potent a remedy as mercury should be most faithfully watched. No judicious practitioner uses it heedlessly or sakelessly. He knows that it is a remedy for good or for evil, and he, therefore, employs it wisely and properly; opportunely, not out of time. As soon as he discovers, by the fetid state of the breath, the red and tumid appearance of the gums, the metallic taste, and the increased flow of saliva, that the object of its exhibition has been attained, he either omits it altogether, or gives it only in very small quantity, and at long intervals. He does not persist in its administration, as was once the custom, until the tongue is too big for the mouth, the teeth drop from their sockets, articulation, deglutition, and even breathing are almost impossible, and the countenance presents a distorted and hideous aspect; he simply touches the gums, maintaining the impression thus made, if necessary, on account of the continuance of the morbid action, or letting it die out, if the disease has been arrested.

There are certain persons who, from idiosyncrasy, or the former use of mercury, cannot take this medicine, even in the smallest quantity, without being violently salivated. To avoid this occurrence, so exceedingly disagreeable both to the patient and the practitioner, due inquiry should always be made with a view of ascertaining this fact, previously to the administration of the remedy. On the other hand, there are persons who cannot, under any circumstances, be constitutionally impressed with mercury, however largely it may be used. They are mercury-proof. It apparently fails to enter the system in any form, combination, or mode of exhibition. In such cases, and also when the system is not as prompt in responding to the effect of the medicine as is desirable, the article should be conjoined with some

nauseant, as ipecacuanha or tartar emetic, so as to produce more thorough relaxation of the system. The operation of the medicine may also be aided with frictions of oleate of mercury upon the groin, the inside of the thighs, the arm, and axilla, thrice in the twenty-four hours, for fifteen minutes at a time, the inunction being performed near a fire, with the hand well protected with a pair of gloves, otherwise the assistant may salivate himself long before he succeeds in affecting the patient. One drachm of the oleate will suffice at each application. Employed in this way, the effect is sometimes more rapid than when the medicine is given internally, although the constitutional impression is more mild and evanescent.

Not unfrequently, especially in persons of very delicate skin, the effect of the remedy may readily be obtained by wrapping around each arm a broad piece of flannel, well smeared with the oleate, and worn until the gums are slightly tender, a small quantity of the preparation being added once a day.

Rapid ptyalism may be effected by the use of suppositories, composed each of a drachm of strong mercurial ointment, rendered stiff with a little tallow, and inserted into the rectum every eight hours, the bowels having been well emptied previously, and then locked up with a full dose of opium in order to secure retention. The gums under this remedy occasionally become quite tender within the first twenty-four hours, and in hardly any case does the time required exceed two days.

There are various circumstances which altogether contraindicate the use of mercury in almost any form. Persons of a strumous habit of body, the old, the infirm, the ill-fed, the badly-clothed, and the anemic, are particularly prone to suffer from the use of the remedy, even when exhibited in very small quantity. It is in subjects of this description, more especially, that we witness those frightful ravages of the mouth, teeth, jaws, and cheeks, formerly so common in this country from the reckless and indiscriminate use of this class of medicines.

Finally, if salivation should accidentally set in, the best remedies will be astringent gargles, cooling laxatives, emollient applications to the face and neck, sulphate of atropia, and the liberal use of anodynes, to allay pain and nervous irritation. The lotion which I have found most efficacious is a solution of Goulard's extract, in the proportion of one drachm to eight ounces of water, used every hour or two, the only objection to it being that it discolors the teeth, an effect which, however, soon disappears of its own accord. Gargles of alum, tannic acid, copper, zinc, creasote, and other astringent substances also prove beneficial, especially if not employed too strong. When the inflammation runs very high, leeches to the throat and jaws are indicated; and it may even be necessary to scarify the tongue, to prevent suffocation. Excessive fetor is allayed with chlorinated soda and other suitable means.

Next to atropia, the best internal corrective of salivation, perhaps, is chlorate of potassium administered in doses of fifteen to thirty grains three or four times a day, in a large quantity of sweetened gum-water, or lemonade, to render it more soluble. This medicine seems to act with peculiar efficacy upon the digestive organs, and may often be advantageously resorted to as a prophylactic during the exhibition of mercury. It may also be beneficially employed as a gargle, from one to two drachms being dissolved in a pint of water, and the solution used every two or three hours. In very intractable cases of ptyalism, an emetic of ipecacuanha, morning and evening, often answers when almost everything else has failed.

4. *Emetics.*—Emetics are not as often used now as they were formerly in the treatment of inflammation, their employment having been, in great measure, superseded by cathartics and other evacuants. Their exhibition, at the present day, is limited almost exclusively to cases in which there is marked gastric and biliary derangement, as denoted by the nausea and vomiting, the headache, lassitude, and pain in the back and limbs, which sometimes so greatly oppress the patient in the earlier stages of his illness. When these symptoms are present, and there is no contraindication, an emetic often acts like a charm, not only ridding the stomach of irritating matter, but allaying vascular excitement, promoting perspiration, and, in fact, unlocking all the secretions. The great Desault and his pupils were particularly fond of this mode of treatment in erysipelas, and I have often witnessed its beneficial effects in this and similar diseases. Emetics are, of course, not used in the phlegmasiae of the subdiaphragmatic organs, as gastritis, enteritis, peritonitis, hepatitis, and cystitis, inasmuch as the concussion caused by their action would inevitably prove injurious. For the same reason they are withheld in wounds of the intestines,

in hernia, in fractures, and in dislocations. In cephalic and cardiac diseases they are also carefully avoided.

The best forms of administration are tartar emetic and ipecacuanha; common salt, alum, and ground mustard also occasionally answer a good purpose, their effect being generally prompt and efficient. Apomorphia is a direct emetic, and when given even in a dose not larger than the one-fifth of a grain often acts with great vigor. Whatever substance be employed, it should be followed by large draughts of tepid water, chamomile tea, or infusion of valerian, the latter being particularly beneficial in nervous and hysterical subjects. As a general rule, tartar emetic should never be given, on account of its sedative and irritating effects, to very young children and to persons enfeebled by age and disease.

5. *Depressants.*—Depressants, sedatives, or nauseants, are justly entitled to a high position in the scale of antiphlogistic agents. As their name implies, they are remedies which, by lowering the action of the heart, lessen the momentum of the circulation, and diminish the flow of blood to the affected tissues. This, however, is not the only good they are capable of doing; by the impression which they make upon the nervous and sanguiferous systems, they are instrumental in reëstablishing and in improving the secretions, and in thus indirectly controlling the morbid action. There is, in fact, not a single organ which does not feel, to a greater or less extent, their influence, or which is not brought, more or less, under their dominion. The effect of this operation is often witnessed during the exhibition of tartar emetic in nauseating doses, in the relaxed skin, the softened pulse, the moistened tongue, and the pallid countenance, all bearing testimony to the universal impression of the remedy. Judiciously employed, depressants are among the most valuable and efficient antiphlogistic means we possess, and they have the advantage that they may often be used without any preliminary depletion. Their beneficial effects are particularly conspicuous in inflammation of the respiratory organs, the heart, the eye, the joints, and the fibrous structures, as well as in certain forms of inflammation of the skin and connective tissue. In many of these affections, if indeed, not in all, they have almost entirely superseded the use of the lancet and other evacuants, their controlling influence over the morbid action being generally very decided. Their efficacy is hardly less apparent in many of the diseases of the subdiaphragmatic viscera; but their exhibition here demands greater care and vigilance, as their emetic effects could not fail to prove prejudicial. Their employment is particularly adapted to the treatment of acute inflammation of young, robust subjects, whose systems require to be rapidly impressed in order to arrest the progress of their diseases. Infants, and children, the old, infirm, and decrepit, do not bear their use well, and often sink under their injudicious administration.

The most trustworthy depressants are tartar emetic and ipecacuanha, aconite, veratrum viride, gelsemium and digitalis, the last of which, however, holds a very subordinate rank. Of the depressing effects of bleeding I have already spoken, and pointed out the circumstances under which they may be most readily produced.

Tartar emetic, as a depressant, may be administered in doses varying from the eighth to the fourth of a grain repeated every two, three, or four hours, according to their impression, which should be steadily maintained until the object of the administration of the remedy has been fully attained. It will generally be safest to begin with a small quantity, and to increase it gradually if it be found to be well borne by the stomach. Sometimes the first few doses, even if small, produce pretty active emesis; but this, so far from being injurious, commonly proves highly beneficial, by relaxing the system and opening the emunctories. By and by gastric tolerance will be established, and then the remedy will often be borne in extraordinary quantities, although it is never employed in the enormous doses recommended by Rasori, Thomasoni, and other disciples of the Italian school. In this country, indeed, we seldom give as much at a single dose as half a grain, the average quantity rarely exceeding one-half or one-third of that amount. The Italian practitioners, on the contrary, often gave five, ten, and even fifteen grains at a dose.

When antimony is administered in a proper and persistent manner after the powers of the system have been lowered by general bleeding, its effect is to depress the heart's action still further, to relax the skin, to prevent the tension of the vessels, and to favor the passage of the blood at the seat of the disease. A continuance of the remedy increases the watery portions of the blood, and diminishes the quantity of solid matter, especially the amount of fibrin.

The beneficial effects of tartar emetic, as a depressant, may often be greatly enhanced by the addition to each dose of a small quantity of the salts of morphia, just enough to produce a calming and diaphoretic impression. Such a combination is particularly serviceable in nervous, irritable persons, and in subjects who have been debilitated by intemperance and other causes. When the article, given by itself, is productive of vomiting, it should never be used in any other way. In children, too, such a mode of exhibition is, as a rule, indispensable. Sometimes the medicine may be advantageously administered along with the neutral mixture.

The dose of *ipecacuanha*, as a depressant, varies from a fourth of a grain to a grain and a half, according to the age of the patient, and the article may be used either alone or in combination with an anodyne, as, indeed, is usually found to be best. A nauseant effect may be kept up in this manner almost as long as may be desired, but the impression is less pervasive and far inferior, in every respect, to that of tartar emetic. On this account, however, the medicine is peculiarly adapted to the treatment of inflammatory affections of children, who, as already stated, seldom bear the operation of antimony well.

Whichever of these two articles be employed, it will be well to withhold all drinks from fifteen minutes to half an hour after the exhibition, otherwise they will be very liable to cause vomiting. At the end of this time, however, diluents, cool or tepid, may be used with the greatest benefit, from their tendency to promote relaxation and secretion.

Aconite is a powerful antiphlogistic. The form in which it is usually exhibited is the saturated alcoholic tincture of the root, prepared according to Fleming's formula, the dose of which is from one to five drops, repeated every two, three, or four hours, until it has produced its peculiar depressing effect. The best, because the safest, plan is to begin with a small quantity, and to increase it gradually and cautiously until it brings down the pulse, which, in the course of a few hours, often descends twenty, thirty, forty, and even fifty beats in the minute, the surface, at the same time, becoming bathed with perspiration. In large doses, it is powerfully sedative and anodyne, but it should never be given in this way, on account of its prostrating influence. It is particularly adapted to neuralgic, gouty, and rheumatic affections, and to the higher grades of traumatic fever; and my practice generally is to combine it with sulphate of morphia, as this insures a more prompt and beneficial action than when given by itself.

Veratrum viride exerts a powerful influence upon the action of the heart and pulse, very similar to that of aconite, only, if possible, still more certainly. The dose of the saturated alcoholic tincture of the root, the form of the medicine most generally employed, is from five to eight drops, repeated every two, three, or four hours, until it has sensibly reduced the force, and frequency of the pulse, when it is either suspended or given in smaller quantity. As veratrum viride is an article of great potency, it is impossible to be too careful in its use. Carried too far, it causes nausea and vomiting, excessive prostration, faintness, vertigo, dimness of sight and other dangerous symptoms. It is applicable to the same class of cases as aconite, and may be given either by itself or in union with morphia, or morphia and tartar emetic. The best means for counteracting its depressing effects are opiates and alcoholic stimulants.

Gelsemium, like aconite and veratrum viride, is a powerful arterial sedative, lowering the heart's action, relieving congestion, and unlocking the secretions. It is particularly applicable to inflammatory disorders attended with neuralgic pains, valvular disease of the heart, and the rheumatic or gouty diathesis. It may be administered in the form of fluid extract, in doses of five to ten drops, or that of a saturated tincture, in similar quantities, repeated every three, five, or eight hours, according to the nature and urgency of the case, its effects being carefully watched.

Of *digitalis* I have not been led to form a very favorable estimate as a depressant or sedative. I was formerly in the habit of employing it a great deal in various forms and combinations, as well as in various forms and stages of inflammatory disease, and yet it would be difficult for me to recall a solitary case in which I derived any appreciable benefit from it. I have, therefore, of late years, altogether abandoned its use.

6. *Diaphoretics.*—Diaphoretics, in their mode of action, bear the same relation to the skin as cathartics bear to the bowels. They constitute, therefore, a highly important class of remedies in inflammation, from the faculty which they possess of restoring and modifying the cutaneous perspiration, the suppression of which is so frequent a source of disease.

As the quantity of perspiration daily thrown off by the skin, in the normal state, varies from twenty to thirty ounces, the retention of such an amount of material in the system must necessarily exert a most prejudicial influence upon the suffering organ. The importance of a critical sweat, as it was called by the ancient physicians, in arresting disease, has long been familiar to the practitioner, and the employment of diaphoretics is only an attempt to imitate nature's efforts, in removing a cause of morbid action, or restoring a secretion which has been suppressed by the changes which that action has induced in the general system. As in the case of purgatives, depletion should always precede the employment of the remedy, so should it in the case of diaphoretics, a relaxed condition of the body always powerfully predisposing to a favorable action of the medicine.

Although the class of diaphoretics is very large, there are only a few articles that are really at all reliable, or that are much employed by the experienced practitioner. These are tartar emetic, ipecacuanha, and Dover's powder, aided, if necessary, by tepid drinks, and sponging of the surface with tepid water. The spirit of Mindererus, a solution of acetate of ammonium, in combination with a small quantity of spirit of nitrous ether, forms a mild diaphoretic, often advantageously used in low states of the system. The efficacy of antimony, which deserves the highest rank in this class of remedies, will be greatly increased if it be given in union with morphia, the two articles thus counteracting the bad effects which they are so liable to produce if administered singly, at the same time that they subdue the heart's action, relax the skin, relieve pain, and induce sleep. The best form of exhibition is a watery solution, each dose containing from the eighth to the tenth of a grain of antimony, with from one-fourth to one-eighth of a grain of morphia, repeated every two, three, or four hours. Ipecacuanha is adapted chiefly to children and old persons, and to the latter stages of the disease, and may be given alone, or, what is preferable, with some of the preparations of opium. The ordinary dose of Dover's powder, for an adult, is ten grains, to which, especially if there be severe pain or great restlessness, I generally add the sixth of a grain of morphia, repeated every eight, ten, or twelve hours. The action of these remedies should always be aided by tepid drinks, and, if there be much dryness of the surface, by frequent sponging of the body with tepid water. During very hot weather, and in high states of inflammation, cool ablutions are often more efficient, as well as more grateful, than warm.

When a speedy and powerful diaphoretic effect is desired, as, for instance, in a severe attack of gout, rheumatism, or acute nephritis, in a young robust person, nothing answers so well as jaborandi, given either in the form of the fluid extract, or that of the alkaloid known as pilocarpin, the dose of the former being one drachm, and of the latter half a grain. Copious perspiration, accompanied by a free flow of saliva and an excess of urea, generally promptly ensues. The only objection to the remedy is its liability to nauseate and to cause excessive prostration, on which account it should be administered with great caution.

When nausea exists along with a very arid condition of the skin, excessive thirst, and inordinate restlessness, the very best diaphoretic is lemon juice, in tablespoonful doses, saturated with bicarbonate of potassium, the salt being added slowly and gradually until all effervescence ceases. The addition of a little syrup of orange-peel renders the mixture more palatable. If an arterial sedative be required, the object may be readily attained by combining with each dose a minute quantity of tartar emetic, as the tenth or twelfth of a grain, or a few drops of tincture of aconite.

Bathing is not often employed in the treatment of acute inflammation, on account, chiefly, of the inconvenience and fatigue attending the operation. In the chronic form of the disease, however, it is frequently a remedy of great value, especially in affections of the skin, joints, and abdominal viscera. The water, which may be simple or medicated, is used at various degrees of temperature, the tepid bath ranging from 85° to 92°, the warm from 92° to 96°, and the hot from 96° to 112° Fahr. A very excellent and convenient mode of conveying moist and heated air to the patient's body, as he lies in bed, consists in attaching one end of a tin tube, from three to four feet in length, to a teakettle filled with hot water, the other end being placed under the bedclothes. Copious perspiration usually promptly follows the application, which may be maintained for any desirable period. The foot-bath is occasionally used with advantage, but to derive full benefit from it the patient should be well covered up in bed, his feet hanging in the water placed in a suitable vessel upon a chair, the immersion being continued from thirty to sixty minutes, and aided by hot drinks. The hip-bath is employed chiefly in affections of the genito-urinary organs.

7. *Diuretics.*—Diuretics are medicines intended to restore and modify the renal secretion, which is invariably more or less changed in all acute inflammatory affections. Their employment should, as a general principle, be preceded by depletory measures, and they should never be given in inflammation of the kidneys and bladder. Their administration is usually accompanied by mucilaginous drinks, but these are not at all necessary to their beneficial effects, ordinary fluids answering quite as well. They may be conveniently arranged under three distinct heads, the first including those articles which, when received into the system, depurate the blood, and increase the quantity of solid matter of the urine, as the nitrate, acetate, and bitartrate of potassium. The second class comprises colchicum, squills, and other vegetable diuretics, which carry off the watery portions of the blood; while the third consists principally of copaiba and cubebs, which not only augment the renal secretion, but exert a peculiar influence upon the mucous membrane of the bladder and urethra, as is evinced in cystitis and gonorrhœa. Of these various articles, the most important, in the treatment of acute inflammation, are nitrate of potassium and colchicum. The former may be given in doses of from fifteen to thirty grains every three, four, five, or six hours, in a large quantity of water. Instead of the salt, spirit of nitrous ether is often employed, especially when a gentle and slightly stimulating diuretic is needed. Colchicum is generally given in the form of the vinous tincture of the seed, in doses varying from ten to fifty drops, several times in the day and night. My practice usually is to employ one drachm along with one-third to one-half a grain of sulphate of morphia every evening at bedtime. In this way the medicine produces a much more decided impression upon the system, as well as upon the renal secretion, increasing its quantity, and freeing it of lithic acid, and probably, also, of other nitrogenized elements. Moreover, it usually acts upon the bowels, bringing away thin watery evacuations, especially when employed by itself; and in large quantities it often vomits. One full dose, administered in this manner at bedtime, is far superior to three or four small ones, which often only fret and irritate the kidneys and bowels, placing them in a condition ill adapted to correct morbid action.

The alkalies, used as diuretics, combine with the acids in the system, and generally pass off as salts. Their value, as remedial agents, consists not only in neutralizing these products, always so injurious when in excess, but in retarding the formation of blood, in dissolving the fibrin, and in diminishing the quantity of albumen.

8. *Anodynes.*—There is no class of remedies which requires a greater amount of nice judgment and correct discrimination, in respect to their selection, mode of combination, and time of administration, than anodynes. The subject, therefore, is one that should be carefully studied by every one desirous of acquiring accurate views of their practical application in the treatment of inflammatory affections. My conviction is that these remedies are not used sufficiently freely, and that they are capable, when properly exhibited, of affording immense benefit, not only in allaying pain and inducing sleep, but frequently also in controlling morbid action, and, consequently, in abridging its course and preventing its ravages.

The same rules, as it respects the premising of depletory measures, are applicable to anodynes as to cathartics. Thus, first, whenever there is plethora, fecal distension, or disorder of the secretions, their correction should, if possible, precede the exhibition of the opiate. Sometimes a full dose of morphia is made to succeed a large bleeding, or an active purgative, the medicine then exercising a decidedly sedative and soothing influence. Administered before the system has been properly relaxed, the medicine rarely fails to increase the vascular action, to arrest the secretions, to produce headache, to prevent sleep, and to augment thirst and restlessness.

Secondly, the medicine should always be exhibited in full doses, as it will thus make a much stronger, as well as a much more soothing, impression than when it is taken in small, and frequently repeated doses. With the precautions pointed out, an adult will bear, when the symptoms are at all urgent, from two to four grains of opium, or its equivalent of morphia, every twelve, eighteen, or twenty-four hours. The effects of the remedy must be steadily watched, especially if the patient is a child, or if there is any undue cerebral excitement. Should the pulse, under its influence, increase in fullness and vigor, the skin become more hot and dry, or the vigilance and restlessness augment, repetition is temporarily suspended, until, by further depletion, the system is placed in a more favorable condition for its reception.

Thirdly, the best period for the exhibition of the medicine, when there is no immedi-

ate necessity for its use, is towards bedtime, the patient being thus more likely to obtain quiet and refreshing sleep after the removal of light and other external stimulants.

Fourthly, when there is excessive pain along with great dryness of surface, and the depletion has already been carried to a sufficient extent, the anodyne should be combined with a diaphoretic, as ipecacuanha, or, what is better, tartar emetic, or, instead of this, a full dose of Dover's powder is given.

Anodynes are particularly beneficial in inflammation attended with violent pain, which, by its persistence, might rapidly wear out the powers of life. Their value cannot be too highly appreciated in the phlegmasias of the skin and connective tissue, the joints, the subdiaphragmatic viscera, the eye, ear, pleura, heart, and respiratory organs. Within the last twenty years enormous doses of opium have been given in peritonitis with the most happy results, and the same mode of treatment might, there is reason to believe, be advantageously extended to inflammation of many of the other parts of the body. The importance of absolute rest to the affected organ is universally conceded, and is daily witnessed in the management of external inflammation. Instinct alone is often sufficient to secure it, but when this fails, the surgeon endeavors to procure it by means of various mechanical appliances. In the internal phlegmasias no such means are applicable, but here the object may readily be obtained by opiates, given in full and sustained doses to control the movements of the suffering structures. In gastritis nothing so promptly and effectually quiets the muscular fibres of the stomach as a suitable quantity of morphia; and the same treatment has long been successfully employed in dysentery, or inflammation of the lower bowel. In cystitis the most effectual remedy for allaying the excessive spasm and the incessant desire to urinate, is a full anodyne. In pleuritis and pneumonitis, how is it possible to afford rest to the lungs and respiratory muscles, except by the same means? The more quietly the parts are kept while laboring under disease, the sooner, other things being equal, will the patient recover from its effects, and the less pain will he be compelled to endure from the constant and rude contact of the affected surfaces upon each other. Even in inflammation of the brain and its meninges, after proper depletion has been practised, anodynes are frequently indispensable, not only to allay pain and induce sleep, but to control the morbid action. And how do they do this? Simply, in the first place, by subduing the action of the heart, and thus preventing it from sending to the brain its accustomed quantity of blood; and, secondly, by making a direct impression upon the brain itself, thereby, in some degree, controlling its movements, so injurious both to its own substance and to its coverings, when thus affected. Anodynes, in most of these cases, as well as in many others, literally constitute nature's splint.

The best anodynes are opium and its different preparations, as the salts of morphia, codeia, laudanum, and black drop. These may be given either by the mouth or by the rectum, double the quantity being usually required to produce the same effect in the latter as in the former case. When a person cannot bear opium in any form, a substitute should be sought in lupuline, hyoscyamus, aconite, Indian hemp, and kindred articles; or, in what I have generally found to answer very well, a union of morphia, tartar emetic, and bicarbonate of potassium, neutralized by lemon-juice.

Many persons bear codeia better than any other form of opium, as it relieves pain and tranquillizes the system, without inducing any cerebral disturbance. The ordinary dose is from half a grain to a grain. Battley's sedative, a watery infusion of opium, sometimes agrees better with the system than any other preparation of opium, the average dose for an adult being about twenty drops.

Hypodermic injections of morphia are much employed, and very justly so, in sleepless and painful conditions of the system, whether the result of inflammation or of other causes, the relief thus obtained being almost instantaneous, without any of the unpleasant effects of morphia when administered by the mouth or rectum. The quantity of the salt should not exceed, at first, on an average, one-fourth of a grain, from which it may be gradually increased to one-half, three-fourths, or even an entire grain, according to the exigencies of the case, the effects of the remedy being always carefully watched.

Finally, there is a condition of the system in which a patient is "too weak to sleep," and in which anodynes, as usually exhibited, instead of being beneficial, are decidedly injurious. This species of exhaustion is often witnessed in inflammation consequent upon severe shock and loss of blood, and is generally most readily controlled by chloral and bromide of potassium, tonics, stimulants, and nutrients, taken as freely as the tolerance of the stomach will admit. As soon as the strength has thus been recruited, recourse may be had to opiates, and now with a prospect of marked advantage, especially if they be

conjoined with some mild diaphoretic, as Dover's powder, spirit of Mindererus, or morphia and acetate of ammonium.

Bromide of potassium is a most valuable remedy in all low forms of inflammation, attended with loss of sleep, unusual nervous excitement, and irritability of the stomach. It should be given in full doses, as from twenty to thirty grains, every two hours, or even more frequently, until the object is attained, when it may be repeated at longer intervals. In the excitement consequent upon delirium tremens there is no article which, according to my experience, produces such prompt and decided relief as bromide of potassium in large and sustained doses.

As a speedy, trustworthy soporific, there is no medicine at all comparable to hydrate of chloral. Its great advantage is that it rapidly induces sleep, without being followed by any of the disagreeable effects of opium and its different preparations. The only objection to its use is its unpleasant taste, but this is generally easily counteracted by giving it in union with syrup of orange-peel. The full dose is thirty grains, repeated every few hours, according to the exigencies of the case. One-third of that quantity often produces a most decidedly hypnotic effect in low states of the system. When the object is to subdue pain, as well as to promote sleep, the chloral may generally be advantageously combined with morphia, from ten to fifteen grains of the former to one-sixth of a grain of the latter constituting a suitable dose in ordinary cases.

Sponging the surface of the body and limbs with tepid, cool, or cold water, as may be most agreeable to the feelings of the patient, often exercises a most salutary influence in cases of insomnia, especially when there is inordinate heat of the skin, tranquillizing the system, promoting perspiration, and inducing healthful and refreshing sleep, when everything else fails.

9. *Tonics.*—There are few cases of acute inflammation, of any severity, in which tonics do not, sooner or later, prove indispensable elements of treatment. Very frequently, indeed, their exhibition is required at the very outset of the disease. This is especially true of persons whose constitution has been exhausted by severe shock, loss of blood, habitual intemperance, or the depressing effects of malaria, contagion, or blood-poisoning. In all these cases, and others of a similar character, depletory measures are either entirely inadmissible, or applicable only in a very limited degree. The general perturbation, in fact, is often feigned rather than real, and it not unfrequently vanishes in a few hours under the influence of a mild purgative or an anodyne diaphoretic. Active remedies would only expedite the downward tendency by still further exhausting the powers of life. In all the more violent inflammatory assaults, there is a period when tonics are indispensably necessary. The system, enfeebled by the conjoint effects of disease and depletory measures, must be upheld at all hazard. Tonics, stimulants, and nutritious food and drink now come in play, and must be freely administered. The empty bloodvessels and the impoverished tissues must be replenished and improved by all suitable means.

Among the more important tonics are the different preparations of bark, especially quinine, cinchonia, and Huxham's tincture, the various forms of iron, as the sulphate and the tincture of the chloride, the bitter infusions, the mineral acids, as the nitric, phosphoric, and sulphuric, alcohol and wine. Much judgment is required in the use of these articles, both as it regards their doses and the time and mode of their administration. They may be given either separately, or in various forms of combination, according to the exigencies of the case, or the object which they are intended to fulfil. When there is flatulence or nausea, some corrigent, as ginger or capsicum, may often be advantageously added to the prescription. Of all these articles, by far the most valuable, as a general rule, are quinine and the tincture of the chloride of iron, with brandy, whiskey, or wine. The dose of the former ranges, on an average, from two to three grains every three or four hours; of the latter, from fifteen to twenty drops. The efficacy of these two medicines is often greatly enhanced by giving them in union with each other. Of all the tonics and stimulants, however, the best and most trustworthy, unquestionably, is alcohol, which may frequently be taken in enormous quantities in all low states of the system, however induced. The choice of the form may generally, very properly, be left to the taste of the patient. A good plan is to vary the prescription occasionally, as one article becomes disagreeable another taking its place. The effect must of course be carefully watched. Wine is frequently preferred to brandy or whiskey. Port, sherry, and Madeira are the most eligible articles of this class. Champagne may be used when there is nausea, flatulence, or indigestion.

Carbonate of ammonium, formerly so much vaunted in all low, asthenic states of the

system, is now seldom employed as a stimulant, experience having shown that it possesses hardly any such property, even when taken in very large quantity. It may, however, often be advantageously exhibited, after the violence of the disease has disappeared, for the purpose of promoting the absorption and elimination of inflammatory deposits, during the progress of their fatty degeneration. The dose should be large, as from ten to fifteen grains, freely diluted with water, and repeated every three, four, or five hours.

10. *Antiperiodics.*—Antiperiodical remedies very justly occupy a high rank in the treatment of inflammation; for there are few cases of the idiopathic form of the disease in which malaria is not present, in some stage or other, or in which, if it does not act as a predisposing cause, it does not impress its peculiar livery upon the system. Malaria has long been known, especially in our Western and Southern States, to play a most important part in the causation and maintenance of certain forms of pneumonia, in the treatment of which the preparations of bark, in large doses, constitute an essential element, which does more in preserving the life of the patient than any other therapeutic agent. In the treatment of erysipelas, boils, carbuncles, and kindred affections, antiperiodics are generally of immense benefit, and after all serious operations and accidents they are of inestimable value in improving the patient's strength, and promoting the action of other remedies. These remarks are particularly applicable to quinine, the most trustworthy of all antiperiodic medicines. Administered in regularly sustained doses, from two to five grains every three, four, or six hours, it opens all the emunctories, relieves pain and fever, imparts tone to the nervous system, increases the appetite, and lessens the frequency of the heart's action. After severe shock and loss of blood, there is no article of the materia medica which renders so much service in preventing pyemia, erysipelas, and other low forms of disease, as quinine. Other antiperiodics are sometimes used, but they are chiefly adapted to the chronic form of disease, in which they are frequently given with marked success.

11. *Combination of Remedies.*—There are few acute surgical diseases or severe accidents in which a combination of several of the remedies now described may not be advantageously employed. In nearly every case of the kind the patient will be found to be oppressed with fever, thirst, pain, and restlessness; or, in other words, to labor under incited action of the heart and arteries, attended with diminished, if not suspended, secretion, and all the evils consequent upon such a state of the system. To meet the indications of treatment, under such circumstances, there is no prescription which, according to my experience, is capable of conferring greater benefit than what may be termed the saline and antimonial mixture, consisting of the following ingredients:—

> ℞. Antimonii et potassii tart. gr. ijss.
>   Magnesii sulph. ℥ij.
>   Morphiæ sulph. gr. j¼.
>   Acid. sulph. aromat. ℨss.
>   Tinc. veratr. virid. ℨjss.
>   Syr. zingiber. ℥ij.
>   Aquæ destil. ℥x.
> M.

Of this combination the average dose is half an ounce, repeated every two, three, four, or six hours, according to the circumstances of the case. If emesis or distressing nausea ensue, the dose must be diminished. Properly administered, it rarely fails rapidly to subdue vascular excitement, to cause copious perspiration, to allay pain, thirst, and restlessness, to act gently on the bowels, and to induce sleep and general tranquillity. Instead of the veratrum, aconite or gelsemium may be used in similar quantities. Colchicum may be added when there is a rheumatic or gouty state of the system, quinine when there is a tendency to periodicity, and copaiba when there is renal or cystic trouble. The quantity of morphia may be increased when there is much pain.

12. *Antiphlogistic Regimen.*—Under this head are comprised the patient's diet, the ventilation of his apartment, and various other attentions required during his confinement. The subject is one which rarely receives the consideration its importance demands.

Few persons, fortunately, have any appetite during the height of an inflammatory attack, and hence the surgeon seldom experiences any difficulty in regard to the regulation of the diet. The stomach, oppressed with nausea, or a sense of uneasiness, either

loathes food, or rejects it almost the moment it is swallowed. It is well it should be so; for any ingesta, however mild, taken at this period, would only become a source of further trouble, by increasing the morbid action, perhaps already progressing at a furious rate. When the appetite remains, it must be repressed, steadily and courageously, until all danger of over-excitement from its indulgence has been safely passed. The mildest and least nutritious articles only are admissible in the earlier stages of the disease, such as panada, gruel, arrowroot, sago, and tapioca. Not even the lightest animal broth is permissible, unless there is decided tendency to prostration, or an irritable state of the system, clearly dependent upon the want of proper nourishment, as occasionally happens in persons of a nervous, irritable temperament, or who are habitually huge feeders. The drinks should be cooling, consisting of iced water, gum-water, linseed tea, or barley-water, either simple, or slightly acidulated with lemon-juice, tamarinds, or any of the subacid fruits; care being taken that, while they are used freely, they are employed in such quantity as not to produce gastric and intestinal oppression.

As soon as the violence of the disease has abated, or the vital force begins to flag, a more nourishing diet must be employed; and the articles generally best calculated to meet this contingency are Liebig's beef essence, beef-tea, the different kinds of animal broths, vegetable soups, eggs, broma, porridge, and corn starch, along with milk, wine, wine whey, and milk punch, given at suitable intervals, and in sufficient quantity to supply the waste of tissue, blood, and nervous fluid. The return to solid food should be very gradual, lest it rekindle morbid action. The starving cells must be fed slowly, not rapidly. When gastric irritability exists, along with excessive flatulence, nothing generally affords such prompt and effectual relief as small quantities of champagne administered in ice. Acidity, or heart-burn, is relieved with subnitrate of bismuth, or bicarbonate of sodium, either alone or combined with ginger. Water ices and ice cream are nearly always admissible in every stage of inflammation.

Koumiss, or milk prepared with yeast and sugar, closely bottled, and kept in a cool place, is an excellent article of diet, highly nutritious, grateful to the stomach, and well suited to dyspeptics in low states of the system. It should be made fresh every day, and may be taken at pleasure, either alone or combined with wine, whiskey, maltine, or infusion of hops, according to the taste or wishes of the patient.

Concentrated essence of beef, made of four pounds of meat yielding a pint of soup without water, is a popular article of diet with English practitioners, in all low states of the system, and may be taken more or less frequently in quantities of one to two ounces, according to the patient's wishes and the tolerance of the stomach. Hot toddy is often very grateful, especially when the patient is cold or chilly; and its efficacy may occasionally be much increased by the addition of an egg and a little spice.

When food and drink cannot be taken by the mouth, they should be administered by the rectum, previously washed out with an enema of warm water, or if there be no contraindications, the bowels should be evacuated by a gentle laxative. In this manner, life may often be prolonged for weeks, and even months. The articles most worthy of reliance as sustenance are defibrinated blood, beef essence, Liebig's extract of meat, animal broths, milk, cream, and raw egg, either alone or combined with brandy or whiskey, from two to five ounces being slowly injected, with a well-warmed syringe, every three, four, or six hours. If the bowel is irritable with a tendency to reject the fluid, a little morphia, laudanum, or acetate of opium, may advantageously be added. Thirst is assuaged by gargling with cold water, by freely sponging the body, and by injecting, occasionally, if necessary, water into the rectum. When the vital powers are greatly exhausted, and all sources of nourishment are unavailing, life may occasionally be prolonged, if not actually saved, by the transfusion of blood, or even of milk. The effort, at all events, is worthy of trial under similar circumstances. The inhalation of oxygen or of the vapor of alcohol is sometimes serviceable.

The promptings of nature should not be disregarded during the progress of recovery; their tendencies are generally wholesome, and they should, therefore, be gratified to at least a reasonable extent, unless there are well-marked contraindications. Acid drinks and food are particularly apt to be craved, and a moderate use of them is highly beneficial, not only in whetting the appetite, but in promoting digestion, by supplying the exhausted stomach with substances tending to atone for the want of a due amount of gastric juice, so essential to healthy chymification. Improper indulgence is, of course, avoided, and care is also taken that the articles are of such a character as to prevent the occurrence of acidity and flatulence.

Rest of mind and body must be carefully observed. The importance of this is so self-

evident that it need not be enforced by any labored argument. Whatever has a tendency to excite the heart's action must necessarily increase the momentum of the circulation, and, through it, the inflammation. In all severe attacks the patient must keep his bed, from which he must not rise even to answer nature's calls; light and noise are carefully excluded from his apartment, especially in inflammation of the eye, brain, and ear; and no persons should be permitted to be about him, except his immediate attendants. Many a patient is killed by the kindness of his friends and relatives. Sexual intercourse must be scrupulously avoided during convalescence. Any excitement of this kind is not only exhausting, but has occasionally proved fatal.

A frequent change of posture is indispensable to the comfort and well-being of a sick person, and should be effected with the greatest possible caution, especially when there is uncommon debility. Violent pain, loss of sleep, excessive constitutional irritation, and dreadful bedsores are sure to follow, in all low states of the system, when this precaution is neglected. When the patient is exhausted from shock or hemorrhage, as after a severe injury or a capital operation, care must be taken not to raise his head too suddenly, or to prop him up with pillows, as he will need all the blood that the enfeebled heart is able to propel to the brain. The bed and body clothes should be kept perfectly smooth, otherwise the wrinkles will be sure to become a source of annoyance, if not positive suffering. The mattress should be soft and elastic, and the sheet pinned fast to the edge of the bed. In case of carious disease or injury, a water-bed will be the most comfortable. Frequent change of posture is especially demanded in paralytic patients, on account of their liability to fatal attacks of bronchitis and pneumonia, from the habitual stasis of blood in the posterior parts of the lungs. Bedsores are also exceedingly prone to occur in this class of sufferers. When the patient is able to sit up in bed, he will experience great comfort from the use of a bed-rest.

The temperature of the patient's room should be regulated, not by his feelings, which are often deceptive, but by the thermometer. On an average, it should not exceed 65°, but in some cases it may range as high as 78°, and in others as low as 60°. The apartment should be frequently ventilated. When it is recollected how soon the air becomes vitiated during sickness, and how necessary a due supply of oxygen is to the proper maintenance of the health, importance of attention to this subject will not be doubted. Cleanliness of the body and of the bedclothes, is another subject of vital moment in the treatment of inflammation, and one upon which few practitioners bestow sufficient consideration. To medicate the inside of a patient, while the outside is neglected, is one of those singular inconsistencies which are daily witnessed in the sick-chamber. I would not insist upon too frequent ablutions and changes of this kind, but they should certainly, in ordinary cases, be effected at least once in the twenty-four hours; care being taken to avoid unnecessary exposure and fatigue during their performance. Even the arrangement of the furniture is worthy of attention, on the principle that an agreeable impression, of whatever kind, is more conducive to comfort and recovery than one of an opposite character.

In all cases of a severe character the thermometer should be frequently used to ascertain the temperature of the body. An elevation of heat is a common occurrence in all inflammatory as well as typhoid states of the system, and, when sudden, great, or persistent, is of evil omen. The heart, lungs, and brain cannot hold out long under the effects of a temperature of 105° or 106°, especially if still advancing, and preceded by chilly sensations, rigors, or horripilations. For meeting such a condition of the system the surface should be freely sponged with tepid water, or, if the patient be strong and robust, in the heat of summer with cool water, with the addition, in such case, of a little alcohol, vinegar, common salt, or chlorinated soda.

II. LOCAL TREATMENT.—The local remedies of inflammation consist of rest and elevation of the affected part, the abstraction of blood, cold and warm applications, compression, destructives, and counter-irritation.

1. *Rest and Position.*—Without rest, steady and persistent, of the affected part, little progress can be made toward the cure of inflammation. The practitioner who neglects attention to this important circumstance, performs only half his duty. The patient, ignorant of its advantages, often continues to exercise the affected organ long after it has become unfitted for the discharge of its functions, much to his present discomfort and ultimate detriment. A simple conjunctivitis, that might be cured in a few hours, is often for the want of a little rest of the eye, urged into a violent and protracted ophthalmia,

perhaps, at length, eventuating in a total loss of vision. An inflamed joint is frequently for the same reason, rendered permanently stiff and useless. Hence, rest is universally regarded as one of the most essential elements of the local treatment of inflammation. In general, it is easily procured, simply by the patient's own efforts; but when this is impracticable, it must be insured by appropriate splints, and other means, applied so as not to interfere with the other treatment. In inflammation of some of the internal organs, as the heart, stomach, peritoneum, bowels, and urinary bladder, the object is attained by the liberal use of anodynes, which, by temporarily paralyzing the muscular fibres of the affected structures, effectually prevent peristaltic motion, and thus place them in a better condition for speedy recovery. But there is a period when rest must not be enforced too rigidly, for, if continued too long, it may be productive of much harm. Its great utility is in the earlier stages of inflammation, when morbid action is gravescent, and for some time after it has reached its culminating point. As soon as recedence has fairly begun, motion, gently and cautiously conducted, is often of great utility.

Not only should the part be kept at rest, but it should also be maintained in an elevated position, the success of the treatment being thereby greatly enhanced. The importance of attention to this point is well exemplified in many familiar diseases. The patient himself is often conscious of it, and, therefore, resorts to it, as it were, instinctively. Who that has ever had an attack of whitlow does not remember the great relief which he experienced from carrying his hand in an elevated position? The influence of position is nowhere more strikingly evinced than in odontalgia. During the day, the patient, while attending to business, is, perhaps, hardly conscious of suffering, but, at night, the moment his head touches the pillow the tooth begins to ache and throb, compelling him to get up and pace his room. In orchitis, the beneficial effects of our remedies are always greatly aided by elevation conjoined with rest of the affected organ. It is quite easy to understand why this should be so. In inflammation, the vessels carry an extraordinary quantity of blood, which is still further increased when the suffering structures are placed in a dependent position, because the flow, not being opposed by gravity, has then free scope, thus crowding the already distended capillaries to the very utmost, and proportionately aggravating the morbid action.

Finally, the inflamed part should also be maintained in as easy a position as possible, mere rest and elevation not sufficing to insure comfort. All restraint must be taken off; all muscular contraction counteracted. Thus, in inflammation of the knee-joint, the limb should recline upon its outer surface, a pillow being placed in the ham, this being the best position for preventing tension. In synovitis of the elbow-joint, the forearm is bent at a right angle with the arm; and in hip-joint disease, the thigh is slightly flexed upon the pelvis, and turned towards the sound one.

2. *Local Bleeding.*—Blood may be abstracted locally by scarification, incision, puncture, leeching, and cupping, each being more or less serviceable, in its own way, in particular cases and under particular circumstances.

The manner in which topical bleeding affords relief is sufficiently evident in some of these forms of depletion, but not very apparent in others. Thus, in scarifying, incising, or puncturing a part, the blood is taken directly from the engorged vessels, which are thus drained of their altered and vitiated contents. If the operation be carried to any considerable extent, as it often may be, especially in the former of these procedures, we may, at the same time, make a powerful impression upon the general system, nearly as rapidly and quite as effectually as when blood is drawn from a vein at the bend of the arm, although, in general, such an effect is neither aimed at nor desired. A similar influence is exerted by leeching or cupping, provided the operation is performed upon the inflamed surface, or in its immediate vicinity. Frequently, however, it is performed at a remote point, and then its mode of action is less intelligible. Thus, in inflammation of the brain, it is difficult to determine how leeches and cups, applied to the nape of the neck, temples, or back of the ear, afford relief to the affected organ. It is certainly not possible, in such a case, to make any direct impression upon the seat of the disease; whatever influence is exerted must be exerted through the general system. This is a self-evident proposition. The vessels of the neck and scalp have no direct communication with the vessels of the brain; hence, in leeching and cupping these parts, we can no more drain the cerebral capillaries than we can drain those of the hand, chest, or any other distant part. It may be assumed, then, that, when topical bleeding is practised by either of the latter methods, its beneficial effects are due, not to any direct drainage of the suffering structures, but indirectly to the depressing influence which it exerts upon

the heart and nervous system, and, through them, upon the morbid action, diminishing the momentum of the circulation, and, consequently, the flow of blood in the capillaries at the seat of inflammation.

Topical bleeding, to be effective, should, as a rule, be preceded by some form or other of general depletion. When the force of the morbid action has thus been broken, the rest of the malady is often easily dealt with by the local abstraction of blood. It is only when the disease is very mild, or unaccompanied by marked constitutional disorder, that this rule should be disregarded. Under such circumstances, the treatment may occasionally be very properly commenced with the application of leeches, cups, or scarification, followed or not, as the exigencies of the particular case may seem to require, by other measures. The manner of abstracting blood topically will be pointed out in the chapter on Minor Surgery.

3. *Cutting off the Supply of Blood.*—Cutting off the current of the circulation from the inflamed structures by ligating the main artery of a limb, is a procedure which has occasionally been employed with advantage, although it is not likely, from its severity, ever to come into general use. The credit of suggesting it is due to Dr. Henry U. Onderdonk, of New York, who practised it successfully in 1813, in a case of wound of the knee-joint. A similar operation was performed in 1824, by Dr. David L. Rogers, upon a man thirty years of age, with equally favorable results. These surgeons were led to believe, from the results of these examples, that the operation, if performed sufficiently early, would often supersede the necessity of amputation, especially in compound fractures and dislocations, as well as in the more violent forms of spontaneous inflammation. The object is to starve the diseased structures by diminishing the activity of the circulation. In 1866, Professor Henry F. Campbell, of Georgia, recalled the attention of the profession to this mode of treatment, in an article in the Southern Journal of the Medical Sciences, in which he adduced a number of cases, chiefly of gunshot injuries of the bones and joints, in which it appeared to have yielded the most gratifying results, the pain, swelling, and tension being almost immediately relieved, and the character of the discharges greatly improved. In five cases in the practice of Dr. D. F. Wright, during the War of the Rebellion, two of the upper and three of the lower extremity, the beneficial effects seem to have been equally striking. In 1867, Mr. C. F. Maunder, of London, successfully tied the femoral artery for the cure of acute inflammation of the leg and thigh, consequent upon a wound of the knee-joint. The chief objection to the proceeding is the grave nature of the operation, which, by cutting off suddenly so great a quantity of blood, might be followed by gangrene of the distal portion of the limb, the very effect which the treatment is designed to prevent. It may readily be supposed that cases might arise which might justify such an undertaking, and yet it is difficult to point them out in a satisfactory manner. How far digital compression, recommended by Professor Vanzetti, of Padua, as a substitute for ligation in such cases, may answer the purpose, remains to be determined. The practice is very favorably spoken of, not only by its originator, but by Neudörfer, Demme, and other military authorities.

4. *Cold and Warm Applications.*—These remedies, which are more particularly adapted to external inflammations, comprise a great number of articles in the form of water dressings and cataplasms, with the character of which every practitioner should be perfectly familiar. Both classes of remedies may be simple or medicated, according to the tolerance of the part and system, and the nature of the morbid action.

(1.) *Cold water* has been employed in the treatment of inflammation from time immemorial; and it is not difficult to conceive how it operates in subduing morbid action. The effect of cold is evidently that of a sedative, lowering the temperature of the part, and causing contraction of the vessels, thereby relieving pain, swelling, and tension. It is particularly applicable to inflammation in its incipient and gravescent stages, while there are, as yet, little effusion, and no serious structural lesion. When the action has reached its acme, threatened suppuration, or, what is worse, tending to gangrene, it must be promptly discontinued. Besides, it is well known, cold, when intense or protracted, may of itself cause gangrene. Young and robust persons usually tolerate such applications much better than the aged or feeble; they are also better borne in summer than in winter. As it is impossible always to predetermine their effects, their action should be carefully watched, in order that, if they become a source of annoyance, they may either be entirely dispensed with, or employed in a modified form. After suppuration has ceased cold

may often again be advantageously employed to relieve vascular engorgement, and to promote the absorption of inflammatory deposits.

The water may be rendered anodyne, astringent, or antiseptic, according to circumstances, by the addition of opium, acetate of lead, or some of the chlorides. The best way to use it is to cover the affected part with a piece of old porous linen, and to direct upon it a constant flow of water in the form of irrigation, from a basin with a stopcock, slung to the top of the bedstead, the limb lying on an oil-cloth trough, from which the fluid is conducted into another vessel standing near the bed. Or the part may be covered with a wide, thin piece of sponge, spongiopiline, or common linen, over which is placed a bladder partially filled with pounded ice. Or the water may be conveyed from the basin by means of a candle wick to a layer of lint upon the inflamed surface, the wick acting on the principle of a syphon. Finally, when ice cannot be obtained, the water may be rendered cold by means of alcohol, in the proportion of one to six parts of the fluid ; by pyroligneous acid and alcohol ; or, by hydrochlorate of ammonium and nitrate of potassium. In whatever manner the fluid be employed, the surface to which it is applied should be constantly exposed to the air, to favor evaporation.

Dry cold is not often used in the treatment of inflammation, although there are cases where it is preferable to cold combined with moisture, as when there is high morbid action in a part greatly debilitated, and rapidly tending to gangrene. The best mode of applying it is in the form of pounded ice, confined in a thin vulcanized India-rubber bag, carefully spread over the affected surface. If a bladder be used, the part should be protected with a thin piece of flannel, otherwise the ice may produce too depressing an influence. The application of pounded ice is particularly valuable in the treatment of acute inflammation of the joints, the result of gunshot and other injuries.

(2.) The use of *warm water* is also of great antiquity, having been employed by Hippocrates and other practitioners in gangrene and various cutaneous affections. It has, however, only been within the last thirty years that it has assumed anything like the rank to which its importance as an antiphlogistic remedy entitles it. I generally give a decided preference to warm water over cold, the impression made by it upon the part and system being usually more agreeable and soothing, while there is much less danger of metastasis, or of a sudden transfer of disease from the external to the internal parts of the body. It is particularly adapted to nervous, irritable individuals, who are easily chilled by cold applications, and to cases in which the inflammation has already made considerable progress, where there is much tension and swelling, or where suppuration is impending, or has already taken place. A good rule, both in regard to warm and cold applications, is to consult the feelings of the patient, using one or the other according to the tolerance of the part and system, or simply so long as they seem to be beneficial. When a change becomes requisite, care must be taken that it is not made too suddenly, or too rapidly, lest it produce harm. Thus, hot applications should be succeeded first by warm, then by tepid, afterwards by cool, and finally, if necessary, by cold, the transition being gradual and wary, not great and sudden, so as to shock the part and system, and thus cause undue reaction.

In the employment of cold water, the part is exposed ; in the use of warm, it is covered. The former does good by constringing the inflamed tissues, and opposing effusion ; the latter, by relaxing the tissues, and favoring effusion.

(3.) *Fomentations*, which may be considered as a species of local bathing, are often very beneficial in inflammation of the joints and some of the internal viscera, from their tendency to relieve pain, tension, and spasm. In cystitis, gastritis, enteritis, and peritonitis, as well as in wounds and other injuries of the pelvic and abdominal organs, their employment can rarely be entirely dispensed with. The most simple fomentation consists of a large, thick flannel cloth, wrung out of hot water, or water near the boiling point, by means of two sticks turned in opposite directions, and applied lightly to the part as hot as it can be borne. If a soothing, narcotic, or sedative influence is required, chamomile flowers, poppies, hops, or, what is much better, laudanum, or laudanum and alcohol, will be found to form valuable additions. In whatever manner they are used, they should be frequently renewed, care also being taken that there are two cloths, so that, while one is taken off, the other may immediately be applied, all danger of shock or undue reaction from exposure to the air being thus avoided.

(4.) *Stuping* is a variety of fomentation, particularly serviceable in affections of the eye, nose, ear, mouth, and throat. It is conducted with a piece of flannel, rolled into a ball, and contained in a small pitcher, which is held at a suitable distance from the affected surface, the cloth being wet as often as it becomes cool. The remedy may be medicated, if desired,

with laudanum, camphor, belladonna, hemlock, or any other article, anodyne, astringent, or sorbefacient.

When it is desirable to apply steam more directly, a funnel may be inverted over the hot fluid, and the tube held towards the affected surface at a suitable distance. Steam may be conveyed to any part of the patient's body, under the bedclothes, by means of a large rubber tube, attached to a small tin boiler, placed upon a table, over a lighted spirit lamp.

(5.) *Poultices*, or cataplasms, are an important class of remedies intended for external application in inflammation, wounds, ulcers, abscesses, and other affections. They are modifications of fomentations, and are made of various substances, either simple or medicated, according to the object intended to be fulfilled. They should not be heavy or bulky, and their consistence should be such as to enable them to accommodate themselves accurately to the surface to which they are applied, without being so tenacious as to adhere firmly to the skin, or so thin as to spread over the neighboring parts. Renewal should be effected as often as they become dry and cold, otherwise they will lose their good qualities and be converted into irritants. In general, it is sufficient to change them thrice a day; but in warm weather, or when there is much discharge, it may be necessary to reapply them every four, five, or six hours. Their temperature should be about the same as that of the body, that is, from 85° to 92° Fahr., and they should be placed directly upon the affected surface in a uniform layer from three to four lines in thickness, a piece of bobbinet, gauze, or thin netting being interposed to prevent adhesion and facilitate removal. For retaining the heat and moisture of a poultice the most suitable appliance is a piece of oiled silk, gutta-percha, or oiled paper.

The action of a poultice is usually limited to the skin, or to the skin and to the parts to which it is immediately applied; it is only when it is composed of very strong materials that its influence is more deeply felt. In using medicated cataplasms, it is necessary, especially in ulceration or abrasion of the skin, to remember that the active ingredient may be absorbed, and thus produce the same effects as when introduced directly into the stomach. Poultices differ very much in their mode of action; thus, some are altogether emollient, that is, they soften and relax the parts to which they are applied, at the same time that they promote exhalation and absorption; some are anodyne; some astringent; some antiseptic; some stimulant. The articles most commonly employed are bread, arrowroot, starch, elm bark, and linseed meal.

The *bread* poultice is made by pouring boiling water upon the crumbs of stale wheat bread, and stirring the mixture in a basin with the back of a spoon until it is of a thick, mush-like consistence. It is then spread upon a piece of folded cloth large enough to cover not only the affected surface, but also a portion of healthy skin. Milk may be used as a substitute for the water, but a poultice, thus prepared, must be more frequently changed, as it soon becomes sour and offensive, and possesses, moreover, no special advantages.

The *arrowroot* poultice is prepared in the same manner as when that article is used for food, only that it is rendered more consistent; the powder being mixed at first with cold and then with a sufficient quantity of boiling water to convert it into a thick, gelatinous paste. Such a poultice is admirably adapted to irritable sores, and deserves to be more frequently employed than it is.

The *starch* poultice is also a very soothing application, and is prepared in the same manner as the arrowroot poultice.

The *slippery-elm* poultice is made of the powdered bark of the slippery-elm, mixed with hot water. It is very light and demulcent, adapts itself readily to any irregularities of surface, and is particularly beneficial in burns. I esteem it as the best poultice that can be made.

The *linseed* poultice consists of ground linseed mixed with boiling water, and stirred until it is converted into a thick, cohesive mass, the vessel in which it is prepared being always well scalded previously. This poultice has the advantage of being very easily made, retaining its heat and moisture a long time, and of having a sufficiency of oil to prevent it from adhering to the surface to which it is applied.

Excellent emollient poultices may be prepared from apples, okra, carrots, turnips, or, indeed, of any of the more tender culinary roots, by boiling them, after having removed the skin, and mashing them into a soft pulp. They possess, however, no peculiar virtues, and are therefore seldom used.

A poultice may be variously medicated. Thus it may be rendered astringent by the admixture of acetate of lead, Goulard's extract, alum, or a decoction of oak bark; ano-

dyne, by laudanum, opium, morphia, poppy-heads, hops, or hemlock; stimulating, by chloride of sodium, vinegar, or port wine; absorbent, by iodine and other articles; disinfectant and deodorant, by Labarraque's solution, permanganate of potassium, thymol, or carbolic, and other acids.

The *fermenting* poultice, employed in foul, fetid, and painful ulcers, in hospital gangrene, and in mortification, used to be prepared by incorporating a pound of wheat flour with half that quantity of yeast, and exposing the mixture to a gentle heat until it swells. A better plan is, after the poultice is spread, to pour the yeast upon its surface. The port-wine poultice, which belongs to the same class as the fermenting, is made in a similar manner, except that it is not boiled.

The *charcoal* poultice, also a good antiseptic agent, although now rarely used, is prepared from recently burned charcoal, reduced to a very fine powder, and mixed with bread, oatmeal, elm bark, or ground flaxseed. The objection to this poultice is its liability to discolor the affected parts, thereby concealing their true condition. This may, however, be obviated, in great measure, by the interposition of very thin muslin.

A cataplasm may be rendered refrigerant by means of a freezing mixture, or a bladder partly filled with pounded ice and spread over its surface. Such an application, however, for reasons already stated, requires great care.

Poultices, even when quite mild, sometimes act as irritants, causing excoriation and tenderness, purulent vesicles, and even minute cutaneous abscesses. Such occurrences are most common in anemic systems and in persons of peculiar delicacy of skin. When any of these effects arise, the use of the cataplasm should be suspended, and the parts covered with warm or cold water, or dusted with oxide of zinc.

5. *Acetate of Lead, Goulard's Extract, and Chloride of Ammonium.*—The efficacy of water-dressings, and of cataplasms, is generally very materially increased by the addition of sugar of lead, Goulard's extract, or chloride of ammonium, either alone or in union with opium. That water alone is a most valuable antiphlogistic agent has been abundantly proved both in civil and military practice, but long experience, founded upon careful clinical observation, has satisfied me that it is far inferior to water medicated with these remedies, all of which possess more or less astringent and sedative, as well as sorbefacient, virtues, and are therefore well adapted to meet the indications that are presented in the treatment of inflammation, whether traumatic or idiopathic, slight or extensive, superficial or deep, recent or advanced. It would be difficult to say which of these agents deserves the preference. They may all be used warm or cold, and in various degrees of strength, according to the desired effect. Chloride of ammonium is especially adapted to those cases of inflammation in which there is extensive effusion of fibrin, or fibrin and blood, and its efficacy is generally materially increased by the addition of a small quantity of vinegar. A solution of the strength of one ounce to half a gallon of water is quite sufficient for ordinary purposes. When combined with an equal quantity of nitrate of potassium, it lowers the temperature of the part in a remarkable degree, without losing any of its sorbefacient properties. The only objection to it is its liability to cause slight pustulation, especially in persons of a very delicate skin; when this arises, its use must of course be temporarily suspended. Acetate of lead may be used in similar proportions, and is the article I generally prefer as a purely antiphlogistic agent. Goulard's extract is also a very valuable remedy on account of its astringent and sedative properties. The average quantity to a pint of water is about two drachms. When the morbid action is attended with severe pain, opium, laudanum, or morphia will be a most valuable addition, but these preparations must not be employed without great care when there is an abraded surface or an open sore, lest the medicine entering the system too freely should produce a poisonous effect. When opium is used in substance, it should be well powdered, and dissolved in boiling water to extract its active principles.

The best medium for applying these solutions is a double layer of old, soft flannel, of suitable size and shape, well wrung out, and kept constantly wet by pressing the fluid upon it with a sponge; reimmersion, always troublesome, if not painful, being thus obviated. Substitution is effected whenever the cloth becomes soiled and offensive by the discharges. When the application is used warm, a covering of oiled paper or oiled silk is employed to confine the heat and moisture, otherwise the parts are exposed to the air, and the cold may even be increased by means of ice applied in a thin gum-elastic bag.

6. *Nitrate of Silver.*—There is no article which enjoys a higher reputation, as a local antiphlogistic agent, than nitrate of silver; certainly none that is more frequently em-

ployed. Without understanding its precise mode of action, experience has taught us its great value in the treatment of a large number of inflammatory affections, some of which it would be exceedingly difficult to cure without it, while nearly all are more or less benefited by it. Ever since its introduction, in 1826, into practice by Mr. Higginbottom, of England, as a topical antiphlogistic, it has been employed in almost every form of external inflammation, both in a solid and a fluid state. Its beneficial effects in diseases of the eye, throat, and genito-urinary organs have long been well known. In cutaneous affections, too, it enjoys a high and well-deserved reputation. In erysipelas, it is perhaps more frequently used than any other single remedy, iodine alone excepted. Its value in the treatment of this disease, so common in this and other countries, is fully established, both in a prophylactic and curative point of view. In inflammation of the tonsils and fauces, whether the result of ordinary causes, of a strumous diathesis, or a syphilitic taint of the system, no article is so generally employed, or enjoys so great a reputation as nitrate of silver. In gonorrhœa and gleet, in stricture and morbid sensibility of the urethra, in spermatorrhœa, in vaginitis, and metritis, nitrate of silver has become an indispensable means of cure. Indeed, it would be difficult to find an accessible disease, attended with preternatural vascularity and disordered structure, in which its application would not be productive of benefit.

Nitrate of silver may be used as a vesicant, as when it is applied to the skin, or simply as an alterant, or modifier of diseased action; for, as already stated, nothing definite is known of its mode of operation. When employed for blistering purposes, the solid form is usually preferred, the stick being passed lightly but efficiently over the surface, previously well cleansed and a little moistened with soft water, until there is evidence of slight coagulation of the albuminoid matter of the epidermis. A cloth, pressed out of warm water, is then applied, when vesication will soon follow. The same result may easily be produced by a saturated solution of nitrate of silver; but, as the remedy is less manageable, it is not often employed with that view. Unless applied in a very concentrated form, and for an unusual length of time, nitrate of silver never destroys the tissues, or acts as an escharotic.

Solid nitrate of silver is often used with great advantage in ulceration of the mouth and throat, cornea, skin, vagina, and uterus, the application being usually made very lightly, and repeated at suitable intervals. Employed too frequently or too abundantly, it often does immense harm, not only occasioning severe pain, but sometimes seriously aggravating the morbid action. These effects may be produced equally by a strong solution as by the solid stick. A strong collyrium of nitrate of silver has destroyed many an eye, or urged on an inflammation, perhaps on the very verge of resolution, to a most distressing extent. Urethritis is often aggravated, and greatly protracted, by a strong injection of this description. Much judgment, then, it will be perceived, is requisite in the local use of this remedy, not only as it respects its strength, but also the mode and time of its application. Carefully adapted to the exigencies of each particular case, it exerts a powerful antiphlogistic impression upon the diseased structures, diminishing vascular action, relieving pain, and destroying morbid sensibility, often so conspicuous in inflammation of the eye and throat, and which nothing else can so well control.

7. *Iodine.*—Iodine first introduced to the notice of the profession as an antiphlogistic agent by Mr. Davis, of England, is, like nitrate of silver, a most useful topical remedy. It is generally employed in the form of the officinal tincture, either pure or diluted with alcohol. Its great value consists in its alterant and sorbefacient properties, changing the action of the capillary vessels, and promoting the removal of effused fluids. That this is the case is sufficiently apparent from what takes place in erysipelas of the skin, where the effects of the remedy may always be easily watched. Within a few hours after the application the swelling is usually so much diminished as to cause a marked corrugation of the surface, attended with a diminution of pain and hardness; circumstances plainly denotive of lessened vascular activity, and progressive absorption. Similar effects are witnessed when the application is made to an œdematous uvula, scrotum, or eyelid, there being not only no further effusion afterwards, but a removal of what was previously deposited. From these facts, it may be inferred that iodine, locally employed, is not merely a sorbefacient, but also an alterant, or modifier of secernent action.

As an antiphlogistic, iodine is of very great value. In the treatment of erysipelas, I have found no article at all comparable to it as an endermic remedy. It is also of great service in boils, carbuncle, whitlow, corns, bunions, and inflamed, irritable ulcers of the extremities. Its beneficial effects are hardly less conspicuous in active œdema of the

uvula and tonsils, legs, scrotum, prepuce, and pudendum, a single application often sufficing to produce the most marked change in the condition of the part. As a collyrium and an injection, the value of iodine has not been sufficiently tested to enable us to form any definite opinion, but the trials that have been made with it, in this respect, are encouraging, and deserving of repetition.

For external use, the tincture of iodine should generally be diluted with an equal quantity of alcohol, the mixture being brushed on with a camel-hair pencil until the skin is of a deep yellowish, brownish, or mahogany color. The application may be repeated every eight, twelve, or twenty-four hours, according to the exigencies of the case. If the remedy be used stronger than this, it will be very apt to produce severe pain and to excite capillary action; two circumstances concerning which it is impossible to exercise too much caution. When intended for the tonsils, uvula, and other delicate parts, the dilution should, for the reason just mentioned, be still greater.

8. *Compression.*—Compression, as an antiphlogistic agent, is too much neglected, nor is it always judiciously used. That it is capable of doing an immense deal of good, when employed with proper care, and under suitable circumstances, my experience fully justifies me in asserting. Why it is so rarely used, it is difficult to determine, unless it is that practitioners do not possess the requisite skill in its application and mode of management.

Although more particularly applicable to the latter stages of inflammation, compression is not without its value in the incipient and gravescent forms of the disease. Affording support to the affected structures, it is well adapted, when early employed, to give tone to the distended capillaries, enabling them to urge on their sluggish contents, and, consequently, to prevent their effusion into the surrounding tissues. Immense good is often done in this way, as every one knows who has ever treated erysipelas, wounds, fractures, and dislocations, by compression. If two cases of any one of these affections, of precisely the same character, could be treated, one with, and the other without the bandage, simply by the ordinary topical remedies, the difference would be found to be most striking. The compressed limb would be comparatively free both from pain and swelling, whereas the other would be highly sensitive and greatly enlarged, from inflammatory deposits. We see, in such circumstances, how, in the one limb, action is controlled, and how, in the other, it pursues its wayward course. But this is not the only benefit which systematic compression is capable of affording. When judiciously employed, it controls muscular action, and thus prevents spasm, both of which are frequently so annoying in fractures, dislocations, amputations, and various affections of the joints. Another effect, by no means the least striking and important, is the sorbefacient influence which it exerts, rousing the absorbent vessels, and compelling them to remove the fluids that were deposited prior to the employment of the remedy. It is for this reason that compression may be so advantageously used in the latter stages of most of the external inflammations, attended with effusion of serum and fibrin, there being no means known to the surgeon so well calculated to effect this important object, and to assist in restoring the functions of the suffering parts. The treatment of orchitis by compression affords a satisfactory illustration of the mode of action of the remedy under such circumstances. When this disease has been shorn of its violence by depletion, the swelling and induration, consequent upon the morbid action, often promptly disappear under the influence of systematic compression; generally, indeed, in one-fifth of the time they do under the use of mercury and ordinary sorbefacients. The absorption is frequently so rapid as to render it necessary to change the dressings twice in the twenty-four hours. Similar effects are sometimes observed in inflamed and enlarged joints.

The means of compression are the common roller and adhesive plaster, applied in such a manner as to make gentle and equable pressure over the whole of the affected structures. When the part admits of it, the bandage deserves the preference, as it is more easily managed, and equally efficient: but there are certain organs, as the testicle and mamma, where adhesive strips alone can be used. When an additional sorbefacient effect is desired, strips of ammoniac and mercurial plaster may be substituted for the ordinary plaster.

9. *Necrotics.*—Necrotics are remedies designed, as their name denotes, to destroy the germs of certain diseases, as that of chancroid, hydrophobia, and malignant pustule, and to neutralize certain poisons, as that of the snake and of the dead subject. Their action is either curative or prophylactic; most generally the latter.

The most speedy and effectual remedy for an incipient chancroid is the destruction

of the affected tissues with some escharotic substance, as nitric acid, bichloride of mercury, or acid nitrate of mercury. The structures inoculated by the poison of hydrophobia and malignant pustule should be treated in a similar manner, or be excised. When the knife is not admissible, on account of the timidity of the patient, the best remedy, according to my observation, is acid nitrate of mercury, in the form of the officinal solution, applied by means of a soft piece of wood, as a common match, or the point of a probe, inserted, if possible, into the part, and held there until the tainted tissues are completely devitalized. The same remedy, either pure or properly diluted, is admirably adapted to the treatment of phagedenic ulcers and spreading gangrene, by whatever cause induced. It should not, however, be used without due precaution, as it is an agent of great power, and may extend its destructive influence far beyond the diseased limits. The ordinary nitric acid is less manageable than the acid nitrate of mercury, from its liability to diffuse itself over the adjacent parts, and is therefore seldom used as an escharotic. Bichloride of mercury, dissolved in alcohol, in the proportion of two scruples to the ounce, is a most efficient caustic, producing a thin, soft, grayish eschar, which separates in a few days. It is used chiefly in venereal buboes, and acts most promptly when its application is preceded by a blister. A powerful escharotic effect may be produced by a combination of three parts of bichloride of mercury with one of opium, made into a thick paste with concentrated sulphuric acid. The only objection to these preparations is the excessive pain they occasion.

Similar means may be employed for neutralizing the poison of the rattlesnake and other venomous reptiles, and for destroying the virus of wounds received in the dissection of dead bodies. In the former case, free excision is practised, followed by the use of the hot iron, or some escharotic substance ; in the latter, the part is held for a considerable time under a stream of cold water, then well sucked, and next thoroughly cauterized with acid nitrate of mercury.

10. *Counter-Irritants.*—Counter-irritants are remedies which, when applied to the surface of the body, excite a new disease, or a new action, in a part more or less remote from the one originally affected. They are never, or at least very seldom, used until after pretty thorough depletion has been practised, by which the inflammation has been relieved of its violence, as their effects are then always more prompt and decided. The new disease is generally established close to the original one, but occasionally at some distance from it. Thus, in inflammation of the hip-joint, the counter-irritant is applied as near as possible over the acetabulum and head of the thigh-bone, the immediate seat of the morbid action, and so with the other articulations. In disease of the neck of the bladder and prostate gland, it is applied to the perineum ; of the pleura and lungs, over the nearest point of the chest. In inflammation of the eye, on the contrary, the irritation is established on the nape of the neck, behind the ear, or on the arm, not in the immediate vicinity of the suffering organ. Great judgment is often required to determine the precise point where, as well as the precise time when, the new action ought to be instituted. If it be too near the original affection, it may run, as it were, into it, and thus aggravate instead of mitigating the mischief; if, on the other hand, it be too remote, it may entirely fail of the object for which it was employed. Counter-irritation, as already stated, is never resorted to until the system has been relieved of plethora, and the morbid action weakened by other remedies. Used in the height of the morbid action, it can scarcely fail to be productive of local and constitutional disturbance, calculated to exercise a prejudicial influence upon the progress and termination of the case.

Although the class of counter-irritants comprises a large number of articles of a very diversified character, they may with great propriety be arranged under two heads, according to their mode of action, as vesicants, and suppurants.

(1.) *Vesicants* are remedies which, when applied to the skin, elevate the epidermis in the form of blisters filled with serum. They are of great value in the treatment of inflammation, both acute and chronic, and are applicable to a great variety of circumstances, with which the practitioner should be fully acquainted. The articles commonly used for this purpose are cantharides, either in powder or in the form of collodion-liquid, ammonia, and hot fluids. In acute disease these means, especially the first, are always preceded by active depletory measures, otherwise they are liable to do mischief by increasing the local and general excitement. In chronic inflammation, however, they may often be advantageously used at the very commencement of the treatment. The vesicating agent is generally placed as near the affected part as possible ; sometimes, indeed, directly over it.

Blisters, properly so called, are prepared with the common fly ointment of the shops, and vary in shape and size according to the object they are intended to fulfil, or the region to which they are applied. The part, if covered with hair, is previously shaved, and the plaster is confined with a compress and roller, or, what is better, with a few adhesive strips. To prevent strangury, an object of great importance, particularly in nervous persons and young children, the surface of the blister should be sprinkled with a few grains of morphia and camphor. The same end may be attained, although less certainly, by the interposition of a piece of tissue paper, steeped in spirit of camphor. In addition to these precautions, free use should be made of cooling drinks, either alone or in union with spirit of nitrous ether. There is no particular advantage in mucilaginous fluids, as flaxseed tea and gum arabic water, so generally prescribed during the application of a blister, as they do not exert any specific influence upon the renal secretion or the mucous membrane of the urinary passages. If strangury occur, prompt relief may usually be afforded by a laudanum enema, and hot fomentations to the genitals and hypogastric region, aided, if necessary, by a full dose of morphia administered by the mouth, rectum, or skin.

A blister should, on an average, remain upon the part from six to eight hours, unless the skin is very delicate and sensitive, when a shorter period may suffice. In children, in whom the desired effect is usually produced in from two to three hours, it is necessary to be very careful, otherwise violent inflammation and even gangrene may ensue. I have seen horrible suffering, and in two instances, death, follow the application of a small blister in children. In the very aged and infirm, similar accidents occasionally happen. Parts affected with paralysis often suffer severely from the protracted use of blisters. The plaster need not, in general, be kept on until there is thorough vesication ; it is sufficient if the skin is quite red, or if there be here and there a little vesicle, the process being speedily completed by the warm water dressing, or a light emollient poultice. It is of great consequence to remove every bit of the salve, and also not to break the epidermis, but simply to puncture it with a large needle or small bistoury, to admit of the necessary drainage, it being a matter of great moment to exclude the air from the raw surface beneath. The dressings already mentioned may be continued until new skin has formed. Should the surface, however, become red, inflamed, and irritable, bleeding upon the slightest touch, and rendering the patient feverish and restless, recourse must be had to the starch, arrowroot, or slippery-elm poultice, or, what is more soothing than anything else, a thick layer of common white lead paint, covered with cotton, the whole being supported with a roller. A powder composed of equal parts of cinchona and prepared calamine dusted upon the surface is also an excellent remedy. Pencilling the part with a weak solution of nitrate of silver has sometimes a good effect, as has also the ointment of the oxide of zinc, especially when the surface is studded with large irritable granulations.

Cantharidal collodion is a more elegant preparation than the common fly-plaster, and may therefore advantageously take its place, the more especially as its effects are equally strong and lasting. It is best applied by means of a camel-hair brush, the surface to be vesicated being thoroughly coated with it, and the evaporation of the ether restrained by moist patent lint covered with oiled silk. Unless this precaution be used, the article will require nearly as long a time to produce its specific influence as an ordinary blister. The principal advantages of cantharidal collodion are, that it can be more evenly applied to the skin, does not shift its position, is more rapid in its action, and is less liable to produce strangury, especially if it contain, as it generally should, an addition of morphia.

Cantharidine blistering tissue is another elegant preparation for vesicating purposes : easily applied and removed, producing its effects promptly without strangury, and leaving no sores.

Ammonia is used only when a strong and immediate effect is desired, as, for example, in croup, where the inflammation, if not promptly checked, may speedily destroy life. Equal parts of lard and powdered hartshorn produce small vesicles in five or six minutes ; and similar effects follow the application of Granville's lotion or liquid ammonia. Boiling water, the concentrated mineral acids, and the heated iron, cause rapid vesication. All such applications, however, are very painful, and they can never take the place of cantharides. Perhaps the least exceptionable article of this class of vesicants is nitrate of silver, which often blisters the skin in a few minutes, especially when it is very delicate, and has been previously well cleansed. The remedy is particularly adapted to infants and children, as it is never followed by sloughing and other ill effects.

(2.) *Suppurants* are the most powerful of all counter-irritants. They are much more permanent in their character than vesicants, and are therefore more serviceable in eradi-

cating chronic disease. As their name implies, the discharge which they produce is of a purulent nature, and hence they are sometimes described under the name of pyogenic counter-irritants. The class comprises permanent blisters, setons, and issues, which will receive particular attention in the chapter on Minor Surgery.

SECT. III.—CHRONIC INFLAMMATION.

Chronic inflammation is distinguished from acute by a variety of circumstances, which it is of the greatest importance to be able thoroughly to appreciate and understand. Its study, in fact, is of paramount consequence, and it is not placing too high an estimate upon its value when it is asserted that there is much greater merit in being able to diagnosticate a chronic disease than to determine the nature and seat of an acute one. When a lesion declares itself, openly and boldly, by a well-marked train of symptoms, the practitioner must indeed be ignorant, if not positively stupid, if he cannot discriminate with tolerable accuracy between it and other affections which may simulate, or bear some resemblance to it; but it is very different when the malady is of an obscure, chronic character, lurking in the system, no one, perhaps, knowing where, even after the closest and most patient scrutiny. It is under such circumstances that the intelligent pathologist and observant practitioner often appears to the greatest advantage, by turning his knowledge to the best account for his patient.

It does not comport with the design or scope of this work to enter into any of the more minute details of this subject; a large volume might be written upon it, and even then it would not be exhausted. A mere sketch of its more prominent features is all that I shall attempt.

Chronic inflammation is of great frequency, and is liable to appear in all organs and tissues of the body; it is generally a consequence or sequel of the acute form, but cases occasionally arise in which it would seem to be a primary affection. Strictly speaking, such an occurrence is of course impossible; all that is meant when the word is used in this sense, is that the disease which it serves to designate is of so stealthy and insidious a character as to escape, at least for a considerable time, the attention both of the patient and his physician; the person is unwell, perhaps occasionally a little feverish, or the subject of headache, want of appetite, or a sallow complexion and constipated bowels; or, it may be, he has a cough, and a pain in his side; or a joint becomes sore and stiff; and still he is able to go about and attend to business, although he is soon fatigued, and rendered uncomfortable by it. Thus a week, a fortnight, or a month may be passed, when, a careful examination being instituted, the discovery is made that there is a grave disease in some important organ, and that it has perhaps already gone so far as to render recovery absolutely impossible, however skilfully the case may now be treated. The disease has been latent, or nearly so; it has failed to make itself known by any distinctive train of phenomena, and both patient and practitioner have been lulled into fatal security. The morbid action has been lying all this time in ambush, and is now, in the true sense of the term, chronic. Such cases are by no means infrequent, and they should serve to admonish us never to neglect any symptoms, however trivial, in our clinical investigations. A pain, a soreness, a cough, a halt in the gait, may, if properly interpreted, afford useful information in regard to the diagnosis of chronic disease, and should teach us the value and importance of patience and caution in the examination of the sick. The slightest neglect may be fatal; a little spark may kindle a devouring flame.

Chronic inflammation, however provoked, is generally tardy and sluggish in its movements, creating little constitutional disturbance, but not, on this account, the less surely and effectually undermining the part and system. In the acute variety, the action is rapid, bold, daring; suffering is severe; and constitutional response loud and unmistakable. In chronic inflammation, on the other hand, the symptoms are, as already stated, often obscure, if not absolutely masked, and the embers of disease never break out into open flame. The disease may continue for weeks and months; now stationary, smothered, or apparently receding; now advancing, and seemingly almost ready to assume the acute type.

The origin of chronic inflammation is often, if not generally, intimately connected with disorder of the digestive apparatus; seemingly, at all events, the first link in the chain of morbid action is frequently referable to the state of the stomach and bowels, especially to the effects of dyspepsia or constipation. Idiopathic inflammation of the eye and other organs often owes its origin to gastro-intestinal irritation. At other times the

disease is awakened by derangement of the menses, defective action of the kidneys, suppression of the cutaneous perspiration, or disorder of the biliary secretion. Anxiety of mind, grief, anger, fatigue, intemperance in eating and drinking, and inordinate sexual indulgence, are all so many predisposing and exciting causes of chronic inflammation.

The effects of this form of disease are various; if not closely watched and soon checked, it may prove fatal by the induction of serious structural changes, which neither nature nor art may be able to repair. The most common and important of these changes are suppuration, ulceration, softening, adhesion, contraction, induration, and enlargement, according to the intensity of the morbid action, the texture and situation of the affected organ, and the condition of the general system. The formation of pus and molecular disintegration, whether by softening or ulceration, are exceedingly common attendants upon this variety of inflammation, and often proceed to a most destructive extent. Adhesion is most liable to occur in the serous tissues; contraction, in the bloodvessels and excretory tubes. Induration and enlargement usually coexist, although occasionally they occur independently of each other. Examples of these two changes are constantly met with in surgical practice, especially in the lymphatic glands of the neck, axilla, and groin, in chronic disease in and around the joints, in various affections of the skin, connective tissue, and bones, and in inflammatory hypertrophy of the tonsils, testicle, mamma, and prostate gland. When existing in a high degree, they lead to serious functional embarrassment of the affected parts, growing out of alterations of structure, which the best directed efforts of the surgeon often fail to relieve.

Gangrene, as an effect of chronic inflammation, is rare; nevertheless, it is occasionally met with, as is witnessed, for instance, in the mortification of the toes and feet, so graphically described by Pott, and dependent upon ossification, inflammation, or embolism of the arteries. In most cases, when the disease passes into gangrene, it first assumes the acute type, which renders the transition much easier, and, in some degree, a necessary preliminary.

The symptoms of chronic inflammation are generally much less prominent than those of the acute variety; the pain is less, and usually also more dull or obtuse; the discoloration is dusky, livid, or purple; the swelling, often considerable, is characterized by unusual hardness, or by hardness and œdema; and the heat is nearly always less than in acute inflammation. Functional disturbance is variable, being extensive at one time, and slight at another. Symptomatic fever may be entirely wanting, and it is this circumstance which so frequently causes this variety of inflammation to be overlooked, especially when it is of idiopathic origin. In time, the fever may assume a hectic type, or it may be of this character almost from the commencement. When the disease is extensive, or seated in an important organ, adynamic fever generally exists.

The vessels of the affected parts are generally very much dilated and distended with red and white globules, on which account the blood is propelled through them in a very tardy and sluggish manner, strikingly contrasting with the force and rapidity with which it is transmitted in the acute form of the disease, where, especially in its earlier stages, all is power and activity. When the inflammation is very protracted, many of the smaller vessels have a varicose, tortuous appearance, and are so crippled as to be almost unable to send on their contents at all. Hence, congestion, often deep and extensive, is generally present, both at the focus of the morbid action and for a considerable distance around.

Treatment.—In the treatment of chronic inflammation, the indications are, first, to remove the exciting cause of the disease; secondly, to correct constitutional disorder; thirdly, to promote the absorption of effused fluids, and, lastly, to restore the tone of the crippled and dilated vessels.

The removal of the exciting cause of the disease obviously demands the same attention here as in the acute variety of inflammation; whenever it is accessible, it should be promptly disposed of. All officious interference must of course be avoided.

Restoration of the secretions constitutes a most important indication, as it is upon their derangement or suppression that the morbid action in chronic inflammation so often depends. The remedies that are chiefly to be relied upon, for this purpose, are mercury, tartrate of antimony and potassium, iodine, nitromuriatic acid, purgatives, and a judiciously regulated diet.

In placing mercury at the head of this list of remedial agents, I simply desire to show the high estimate that is so justly attached to it in the treatment of chronic inflammation. If its administration is of doubtful propriety in many cases of the acute disease, there are few instances of the chronic in which it may not be beneficially exhibited; and yet,

in making this remark, it must not be understood that it is to be given indiscriminately or sakelessly. Its value is unquestionable, but, still, there are cases and circumstances in which it is utterly inadmissible; this is especially true of those cases of chronic inflammation which are so often met with in scrofulous children, and in persons of enfeebled and broken constitution, where mercury, in almost any form, is generally most pernicious, the smallest quantity sometimes producing profuse ptyalism, or gangrene of the mouth.

In administering this remedy for the cure of chronic inflammation, the surgeon has it in his power to make choice of a much greater number and variety of articles than in acute inflammation, in which he is obliged to restrict himself chiefly to calomel and blue mass. In the chronic form of the disease, he has, in addition, the bichloride, the protiodide and cyanide, which exert a most salutary influence in changing the capillary action of the part, and promoting the removal of effused fluids. Whatever substance be selected, the dose should be very small, and not repeated oftener, on an average, than twice or thrice in the twenty-four hours. The object is to produce a slow and gradual effect, and for this purpose it will generally be necessary to continue the remedy for several successive weeks. Active ptyalism is carefully avoided; it will be quite sufficient if we succeed in obtaining slight soreness of the gums. If calomel be used, a good average dose will be from one-sixth to one-half of a grain.

In children, the most suitable mercurials are blue mass, corrosive sublimate, and gray powder, or mercury with chalk, given either alone or in union with sodium and columba, quinine, or Huxham's tincture of bark.

Iodine and its various preparations, as iodide of potassium, iodide of iron, iodide of cadmium, iodide of ammonium, and Lugol's solution; bromide of potassium; barium; and tartar emetic often exert a most salutary influence over chronic inflammation, and are particularly indicated where a slow, alterant effect is required. With the exception of mercury, I know of no article of the materia medica which produces so powerful an effect as tartar emetic in controlling chronic inflammation, and favoring the absorption of effused fluids. The proper plan is to give it in small doses, as the eighth, tenth, or twelfth of a grain, in combination with some vegetable bitters and a little morphia, three times in the twenty-four hours.

The different acids are sometimes administered with advantage, especially the dilute nitromuriatic, formerly so much employed in the treatment of hepatic affections. They are particularly indicated in chronic syphilitic and scrofulous inflammations, attended with impaired digestive powers.

The bowels must be kept in a soluble condition, the nature and dose of the purgative being regulated by the exigencies of each particular case. The compound calomel pill, which, while it operates on the bowels, and excites the action of the liver and skin, constitutes one of the most eligible cathartics we possess in the treatment of chronic inflammation, accompanied with visceral obstruction.

Particular attention should be paid to the skin. This will appear the more necessary when we consider that, in most cases of chronic disease, the perspiration is either entirely suppressed, or greatly changed in its properties. Frequent ablutions with cool, tepid, or warm water, impregnated with common salt, soap, mustard, or potassa, and followed by dry frictions, often prove highly serviceable. In many cases the cold bath will be found to be extremely valuable, especially if the surface be well rubbed immediately after with a coarse cloth. The renal secretion should also receive proper attention; sometimes elaborate chemical and microscopical examinations will be required to determine its character, and enable us to direct a suitable plan of treatment.

Exercise in the open air, either on foot, in a carriage, or on horseback, often effects a wonderful improvement in chronic inflammation, especially when of long standing, and attended with great debility. At other times, nothing but the most perfect rest will answer the purpose; as, for example, in serious disease of the brain, bones, and joints.

The subject of diet claims special attention in the treatment of chronic inflammation. The indiscriminate use of food in this form of disease cannot be too severely reprehended. Too great abstinence, however, is often as injurious as too great indulgence. All stimulating and indigestible articles should, as a rule, be avoided as likely to increase the local disease, and exercise a prejudicial influence upon the patient's recovery. If the system is inclined to plethora, the diet should be of a strictly farinaceous character, and be limited daily to a few articles, varied from time to time as they become disagreeable to the palate, or offensive to the stomach. If, on the other hand, the patient is pale and feeble, it should be partly farinaceous, and partly animal, the meat being taken at breakfast and dinner, and its effects carefully watched. The different kinds of animal and vegetable broths,

beef-essence, milk, arrowroot, rice, sago, tapioca, hominy, and grits, are all eligible articles in chronic inflammation, and often prove of the greatest service in nourishing and sustaining the system. Their flavor and efficacy may be improved by the addition of spices, wine, or brandy, as may be deemed proper. When the patient is much exhausted, the use of whiskey, brandy, wine, ale, or porter will often be indispensable to recovery. Cod-liver oil may be employed when there is marked debility along with emaciation; rather, however, as an article of nourishment than with a view to the attainment of any alterant effect it may be supposed to possess from the presence of iodine and bromine. The dose should be as large as may be consistent with gastric tolerance.

Finally, in the female, proper regard must be had to the state of the menstrual function; prompt measures being adopted for its improvement, or, in the event of its suppression, for its restoration. There are numerous complaints which owe their origin, either directly or indirectly, to disorder of the uterine functions.

The local treatment of chronic inflammation is generally a matter of paramount importance. It comprises, first, as in acute disease, rest and elevation of the parts; secondly, leeching, scarification, blistering, iodine, and nitrate of silver, especially in the early stages; thirdly, counter-irritation by croton oil, tartar emetic, issues, and the actual cautery; and, lastly, sorbefacients, such as stimulating liniments, embrocations, and unguents, the cold douche, compression with the bandage, or adhesive strips, electricity, and massage, the latter of which is often of immense service. When the parts are hot and tender, solutions of acetate of lead, or evaporating lotions, are generally highly beneficial, if not indispensably necessary. In obstinate cases, electricity is sometimes useful, although its effects have been greatly overrated.

CHAPTER IV.

TERMINATIONS AND RESULTS OF INFLAMMATION.

SECT. I.—DELITESCENCE AND RESOLUTION.

THESE terms are used to denote the restoration of the inflamed structures to their normal condition. The word delitescence is of Latin derivation, and literally signifies to abscond; it was introduced into surgical nomenclature by the French writers, and is employed to designate the sudden disappearance of inflammation, before it has passed through its different stages, and, consequently, before it has occasioned any serious structural changes. It is unquestionably the most desirable mode of termination, and may occur either spontaneously, or from the slightest treatment. A catarrh, caused by exposure to cold, and perhaps threatening to be quite severe, often aborts during a profound sleep induced by a warm bed, or a hot foot-bath and a little morphia. An inflammation of a lymphatic gland of the neck, coming on late in the evening, and attended with great tenderness on motion and pressure, together with considerable swelling, often rapidly disappears under similar measures. An incipient gonorrhœa frequently aborts under the use of a mild injection of nitrate of silver or acetate of lead; and who has not seen a bubo promptly vanish under steady, systematic compression, aided by the application of iodine? Inflammation produced by the presence of a foreign body generally rapidly disappears after the removal of the exciting cause of the morbid action.

The above facts, as well as many others that might be adduced, are pregnant with two most important lessons, one of which is to remove as early as possible the exciting cause of the inflammation, and the other to lose no time in instituting a proper method of treatment for the relief of the morbid action. The object should invariably be to save structure, and the best way to do this is to compel the disease to abscond, or delitesce. Such an event, however, is only desirable when the inflammation can be dislodged more or less completely without any risk of throwing it upon some other and, perhaps, more important organ. Thus, an attack of gout in the great toe would be a trifling affair in comparison with an attack of gout in the heart, brain, or stomach; and hence it would be far better, when there is danger of such a translation of irritation, to let the original disease pursue its course, than to attempt to arrest it by means tending to favor such a result. A severe injection may suddenly arrest an incipient gonorrhœa, but it may do infinite harm by the

rapid induction of orchitis, which perhaps no treatment, however judiciously conducted, may be able to dispel completely under several weeks, or even months.

The sudden disappearance of inflammation from one structure, or set of structures, and its invasion of another, usually known by the term metastasis, suggests the importance of proper watchfulness on the part of the surgeon to prevent such an occurrence ; or, if it have already taken place, of employing such means as shall serve to recall the morbid action as speedily and effectually as possible to its original situation.   For this purpose free use should be made of counter-irritation, in the form of stimulating embrocations, sinapisms, or blisters, aided, if the organ affected be one of great importance to life, by the abstraction of blood and the free use of opiates.   If, in this way, the disease cannot be recalled, the treatment will go far to put a speedy stop to its violence and its tendency to extension.

The term resolution denotes the gradual dissipation of inflammation after the disease has made some progress and done some mischief, but before it has reached the suppura-tive crisis, or committed such ravages as to prevent the affected tissues from regaining their original properties.   With such an issue effusion of serum and lymph is not at all incompatible, as these fluids may be entirely absorbed ; a similar remark is applicable to pus, provided it exist in small quantity, or not as an abscess, in which there is always more or less waste of tissue ; and even to pure blood, which, if not too abundantly effused, or deprived of its vitality, is generally readily amenable to the action of the absorbents.

When resolution is about to occur there is a gradual and steady subsidence of the mor-bid action, as denoted by the changes in the local and constitutional symptoms.   The discoloration, heat, pain, and swelling become less and less through the contraction of the vessels and the absorption of the effused fluids ; the febrile disturbance passes off ; and the part and system, no longer influenced by the effects of the disease, at length regain their normal condition.   Often many weeks, and even several months, elapse before the restoration is finally completed.   The absorbent vessels, kept in abeyance by the vascular action and the effused fluids, are slow to resume their functions ; they act at first hesita-tingly, as if afraid to enter upon their labor, but as the work progresses they acquire con-fidence, and, at length, setting about it in good earnest, they ere long finish their task, drinking in, as it were, all that their oppressors, the secernents, had previously poured out, and thus leaving the parts in a condition to regain their primitive characters.   The bloodvessels usually remain dilated, feeble, and sluggish for some time after the complete subsidence of the disease, and there is also frequently more or less perversion of special sensation.

<center>SECT. II.—DEPOSIT OF SERUM.</center>

A deposit of serum, or of the watery elements of the blood, is a common attendant upon inflammation, and in some cases constitutes, pathologically speaking, the principal, if not the only, evidence of its presence.   The structures which, when thus affected, supply serum in greatest abundance, are the connective and serous, the secernent vessels of which are generally extremely active, even when the disease is comparatively mild.   Large quantities of serum are also occasionally poured out by the mucous membrane of the ali-mentary canal, especially by that of the colon and rectum, as in diarrhœa and cholera. Inflammation of the skin, unless produced by scalds, blisters, erysipelas, and the various bullar diseases, yields this fluid generally sparingly.   Very little is also effused in inflam-mation of the muscles and fibrous membranes, the nerves and vessels ; while tendon, car-tilage, and bone do not afford any, however severe the morbid action.   A similar remark is applicable to inflammation of the parenchymatous and glandular organs, as the lung and liver.   In the connective tissue serous accumulations are particularly liable to occur wherever this substance is very loose and abundant as in the eyelids, scrotum, prepuce, labia, nymphæ, legs, and feet, which are often enormously distended in consequence.   (Edema of the glottis is an example of watery deposit in the submucous connective substance of the edges of the larynx.   In the splanchnic cavities and the movable joints serum often collects in immense quantities ; sometimes as an effect of acute, but more frequently of chronic, inflammation.

Particular epithets are employed to designate certain collections of serum, based either upon the appearance of the part, or the anatomical name of the cavity that serves to re-ceive the fluid.   Thus it is customary to speak of œdema of the glottis, of œdema of the eyelids, and of œdema of the legs, simply because these structures, when thus affected, have a swollen, glossy aspect.   The older writers applied the word anasarca to all aqueous accumulations of the inferior extremities, under the supposition that the fluid was diffused

through the muscles. Dropsy of the leg is another familiar expression. The latter term, however, is generally restricted to collections of serum in the various cavities of the body, as dropsy of the abdomen, chest, head, pericardium, joints, and vaginal tunic of the testicle. Or, instead of this term, a Greek one, either simple or compound, is used, as being somewhat more classical. In this manner a dropsy of the abdomen becomes an ascites; of the chest, a hydrothorax; of the head, a hydrocephalus; of the vaginal tunic, a hydrocele.

Although serum is generally limpid in its appearance, cases now and then arise in which, from the admixture of hematin, bile, or other extraneous matter, it is reddish, dark, yellowish, or even milky. A dark appearance, such as is so generally present in the peritoneum in strangulated hernia, is to be viewed as an evidence of intense inflammation. A similar phenomenon is witnessed in the blebs of incipient gangrene, and in the enormous accumulations of serum which occasionally occur in the limbs in consequence of snake bite and other severe injuries.

The fluid, which sometimes contains flakes of fibrin, pus, and even pure blood, is unctuous to the touch, saline in taste, but free from odor, and is readily coagulable by alcohol, heat, acids, and corrosive sublimate; circumstances which show that it is composed principally of albumen, in combination with some of the earthy salts, especially the sulphates. Its quantity in acute inflammation is usually small, except in the splanchnic cavities, where it is sometimes immense, amounting to many quarts, or even several gallons.

Great diversity of sentiment has been expressed in regard to the kind of action under the influence of which this fluid is produced, some declaring that it may be effused independently of inflammation, while others maintain that inflammation is indispensably necessary. I have long been of the latter opinion, nor is it possible, it seems to me, to arrive at any other conclusion, unless it be assumed that there is no inflammation without suppuration, or, at least, without fibrinous exudation, a doctrine so utterly at variance with the facts of the case as to render its adoption impossible. Inflammation is a very simple process; it requires very little disturbance to induce it, and an effusion of serum often occurs without any of the ordinary phenomena of the disease, as heat, pain, and discoloration. In chronic dropsies, for example, the inflammation is frequently so very slight that, if it were not for the mechanical inconvenience which the fluid occasions, the patient would hardly be conscious of any suffering; and yet, even in such cases, it will generally be found, on dissection, that the serous membrane which furnished the water, exhibits sufficient indication of the lesion in the opaque and thickened condition of its substance. It may be questioned whether mere congestion is capable of producing serous effusion. At first sight such an occurrence would seem to be quite probable; but a careful examination of the subject soon dispels the illusion. Permanent obstruction of the abdominal cava causes ascites, not from mere congestion of the vessels of the peritoneum, but as a consequence of its inflammation, the result of the previous vascular engorgement. It is easy to see that vessels habitually distended must soon take on incited action, followed by abnormal deposits. A familiar illustration of this is afforded in the conjunctiva, where, if the vessels are at all engorged even for a short time, inflammation is sure to follow, unless the exciting cause of the determination is speedily removed. If this mode of reasoning be correct, it follows that obstruction of the circulation, however induced, must, if permitted to continue, be soon succeeded by inflammation, of a grade and character sufficient to cause at least an effusion of serum, if not also of other fluids.

Of the nature of the morbid action, when serum is rapidly supplied, or when it is associated with other deposits, as lymph or pus, there can be no doubt that it is highly inflammatory. The concomitant symptoms, and dissection after death, clearly establish the fact. The rapid and profuse serous exhalations which occur in acute pleuritis, peritonitis, and arachnitis admit of explanation in no other way; they are the appropriate products of these structures, and hence they generally appear very early in the disease.

Effusion of serum is often associated with, if not directly dependent upon, an impoverished and watery condition of the blood, accompanied by a marked decrease of fibrin and red particles. If, under such circumstances, inflammation be lighted up, especially in connective and serous tissues, serum cannot fail to be supplied in large quantities, since, in consequence of the diminution of the plastic properties of the blood, there is nothing to restrain its exudation. Hence such action is very prone to be followed, externally, by anasarca or œdema, and internally by dropsy.

The symptoms produced by this deposit are such, mainly, as are denotive of mechanical obstruction. In the eyelids, glottis, scrotum, prepuce, vulva, and legs, it is marked by a soft, inelastic swelling, which pits on pressure, and imparts a peculiar glossy appearance

to the affected surface : attended, especially in the inferior extremities, with pain, heat, and more or less discoloration, usually of a pale dusky hue. A sense of distention is also commonly a prominent symptom. In œdema of the glottis there is serious impediment in the respiratory functions, while in accumulations of water in the splanchnic cavities there must necessarily be more or less oppression, with displacement of the contained viscera. A large collection of water in the chest may not only cause collapse of the lung on one side, but greatly encroach upon the opposite one, and at the same time throw the heart completely out of its natural position, depress the diaphragm, and tilt up the intercostal spaces so as to give the thorax a vaulted configuration. In infiltration of the connective tissue of the leg, feet, scrotum, and vulva, the fluid may, by its pressure upon the capillary vessels, cut off the supply of blood from the skin, and thus become a cause of mortification, as is exemplified in certain forms of erysipelas and anasarca.

In the treatment of internal serous effusions, the leading indication is to promote the absorption of the offending fluids by the use of hydragogue cathartics, diuretics, and mercurials ; followed, when these means fail, by an operation for their efficient evacuation. The most important cathartics, after thorough purgation, are jalap and bitartrate of potassium, citrate of magnesium, and elaterium, given in doses proportioned to the strength of the patient and the tolerance of the stomach and bowels. These remedies, as well as others of a kindred nature, produce their beneficial effects by establishing a drain upon the serous capillaries of the alimentary canal, which leads indirectly to the absorption of the serous accumulation. When mercurials are required, as in case of obstruction of the portal circle, with deficiency of the hepatic secretion, the most eligible articles are calomel, blue mass, or corrosive sublimate, either alone or in union with elaterium, squills, digitalis, or antimony, according to the nature of the collateral disorder. Deficiency of the renal secretion must be corrected by suitable diuretics.

When the accumulation of serum is very great, as in dropsy of the chest, abdomen, or pericardium, all internal treatment will be likely to prove abortive, as it is then generally impossible to rouse the absorbents, the pressure of the fluid keeping them in a crippled and paralyzed condition, altogether incompatible with the healthy exercise of their functions. Hence, instead of wasting time and the strength of the patient, as is unfortunately too often done in such cases, early vent should be afforded to the pent-up matter. Serious and even fatal errors are constantly committed for the want of early interference with the trocar in these accumulations. It must not be forgotten that purgative, diuretic, and alterative remedies, if available at all, can prove beneficial only at the expense of much distress and exhaustion of the system, which too often leave the sufferer, in the event of his recovery, with permanently shattered health. An operation, on the other hand, generally promptly remedies the urgent symptoms, and places the part in a much more favorable condition for the efficient action of sorbefacient medicines.

Local remedies are available chiefly in serous effusions in the external parts of the body. In œdema of the extremities great benefit is often derived from steady and persistent elevation, and regular, equable compression with the bandage, extending upwards from the distal portion of the limb. In this way support is given to the weakened capillaries, while a salutary stimulus is imparted to the absorbents, increasing their action and thus favoring the removal of effused fluid. This treatment often derives important aid from frictions with sorbefacient unguents, liniments, and embrocations, and the application of dilute tincture of iodine. When the distention is inordinate, or threatens to pass into gangrene, early punctures and even free incisions are called for, although, generally speaking, they are objectionable, as they often bring about the very disease they are designed to prevent. In œdema of the glottis nothing short of prompt and decisive scarification can save the patient from suffocation.

SEC. III.—LYMPHIZATION OR PLASTIC EXUDATION.

Lymphization is the act of separating lymph or plasma from the blood and depositing it in the organs and tissues, or upon their free surfaces. The term bears the same relation to the substance which it serves to designate that the word suppuration bears to pus, the product of that act. As signifying the same thing, the phrase " fibrinous exudation," or " inflammatory exudation," is often used.

There is seldom any inflammation, however slight, without some deposit of lymph. Indeed, in many cases, and in certain situations, it constitutes almost the only product of the morbid action. Thus, in croup and peritonitis, the chief evidence of the existence of these diseases, after death, is the presence of lymph ; in general, however, it is associated

with other deposits, especially serum, which is often poured out along with it in large quantities. When the inflammation is at all severe, and particularly if it have already made considerable progress, there may be, in addition, puriform matter, pus, and even pure blood. Its presence, whether occurring singly or combinedly, is generally denotive of a higher grade of action than the mere effusion of serum.

The capacity of furnishing lymph, in inflammation, is possessed in different degrees by different organs and textures, depending upon the peculiar nature of their structure and organization. The serous membranes, especially the pleura and peritoneum, the connective tissue, and certain portions of the mucous system, as the faucial, laryngeal, intestinal, and uterine, yield it very freely. Very little is effused, under any circumstances, by the fibrous membranes, the muscles and their tendons, the vessels, nerves, cartilages, and bones, except in fractures and other injuries, in which it is sometimes thrown out in great abundance. In some of the parenchymatous organs, as the brain, liver, and kidneys, it is usually supplied very sparingly, whereas in inflammation of the lungs and spleen it is often effused very freely, leading to rapid solidification of their proper structure. Large quantities of lymph are sometimes exhaled during the progress of abscesses, many of which it serves to inclose in a distinct cyst, known as the pyogenic membrane.

Lymph is generally poured out very early in the inflammatory process, and often continues for an indefinite period, increasing and declining with the disease. It is surprising how soon it sometimes shows itself. From experiments that I have performed upon the inferior animals, as well as from observations upon the human subject, I am convinced that it begins much earlier than is usually supposed. In 1841, I had repeated proofs of this fact, while engaged in an elaborate series of experiments upon dogs, with a view of elucidating the nature and treatment of wounds of the intestines. I found, in many of these animals, that the bowels had become extensively adherent, not only to each other, but likewise to the walls of the abdomen, within a very few hours after the operation. In the case of a gentleman whose abdomen I opened, on account of a twist in the small intestine, although death occurred at the end of four hours, nearly the whole peritoneum, visceral and parietal, was coated with a thin film of fibrin, of which hardly any traces existed anywhere at the time of the operation. In another case, that of a young lad, who died within nine hours after he had been shot in the side, the ball wounding the abdomen, diaphragm, and chest, large quantities of lymph were seen both upon the peritoneum and the pleura. The flaps made in an amputation become speedily glazed with fibrin, and the edges of an incised wound frequently adhere quite firmly within a very short time after their approximation.

From the preceding facts, it is evident that the exudation of lymph generally begins at an early period of the inflammation, and that, under favorable circumstances, it proceeds with great vigor. When the reverse, however, is the case, it advances comparatively slowly, or it may even fail entirely. Such an event will be most likely to occur in low and depraved states of the system, attended with anemia and lesion of the innervation.

Plasma, considered as an effect of disease, is a direct product of the vessels of the affected structures, the process by which it is elaborated being one of a vital character, analogous to, if not actually identical with, secretion. Virchow maintains that it has an extravascular origin; or, in other words, that it is a local product of the tissues, on and in which it is found, being essentially composed of the material generated in the inflamed part itself through the changes in its condition. He denies that there is, in the ordinary acceptation of the term, any inflammatory exudation whatever; or, what is the same thing, that there is any actual transudation of the blood-liquor. However this may be, lymph is a vital, organizable, proliferous fluid, susceptible of great changes in its composition, and capable of playing a most important part in injury and disease.

Recently effused lymph is of a whitish, pale straw, or opaline appearance, although now and then it is somewhat reddish, from the admixture of hematin. In cases of protracted jaundice, it is occasionally of a pale orange hue. It is of a soft, unctuous consistence, like hot glue, or a thin solution of starch, is destitute of odor, has a faint saline taste, and is essentially composed of fibrin in union with albumen and serum. Immersion in alcohol renders it tough, and changes its color from white to buff.

Lymph is a vital, organizable fluid, identical in its composition with the buffy coat of the blood. Under the microscope it is found to consist of numerous globules, analogous to colorless blood corpuscles, of a spherical shape, nearly homogeneous, and about the $\frac{1}{2600}$ of an inch in diameter. Delicate fibrils, straight, parallel, and interspersed with innumerable granules, are also visible in it. Although lymph is always poured out in a fluid state, it soon arranges itself in various forms; now as an amorphous mass; now as

a tube, as in the larynx and bowel; at one time as a lamella, and at another as a distinct band; its conformation being materially influenced by that of the organ, tissue, or cavity in which it is effused.

Plasma does not always exhibit the same appearances either under the microscope or to the naked eye. In this respect it shares the same fate as other morbid products. Any differences that it may present are entirely due to differences in the state of the blood, the part and the system in different individuals, localities, and grades of the morbid action. Corpuscular lymph, as it has been termed by Rokitansky, differs from ordinary only, or chiefly, in having a greater number of exudation globules, and less of healthy fibrin. It is generally met with in persons of deficient vital powers, with an impoverished state of the blood, and soon manifests a disposition to break down and become effete. In young, robust persons the lymph poured out in inflammation is generally very firm and abundant, with a strong cell-force, and a tendency to rapid organization. In scrofulous subjects it is almost wholly corpuscular. Its constitution is also materially influenced by the nature of the affected structures and the character and intensity of the morbid action.

Fig. 4 represents a portion of recently effused corpuscular lymph, opaque, white, friable, and magnified about 380 diameters, from an inflamed pleura. It is composed of colorless corpuscles, and granular matter in a hyaline matrix. In the lower part of the figure the corpuscles are shown as floating in serous fluid. In fig. 5, magnified 800 diameters, the structure of the effused matter is somewhat different. It forms, in fact, a sort of false

Fig. 4.   Fig. 5.

Fig. 5. Recent Lymph, forming False Membrane.
membrane, the croupous exudation of the German authors. Numerous corpuscles, more or less globular, a few epithelial cells, and granular matter, are seen to be interspersed through filaments of fibrin.

The period at which the organization of this substance takes place varies with a number of circumstances, of which the most important are, the plasticity of the effused matter, the nature of the affected tissues, and the state of the general system. To enable it to attain this point at all, it must have a strong cell-life, formative power, or cell-force; if this be wanting the development of cytoblasts will either be impracticable, or so imperfect as to be soon arrested, or, at all events, very much impaired. When everything is favorable, the development proceeds very rapidly; cells and nuclei are formed in great numbers, and these, connecting themselves with each other, are gradually spread out into fibres, lying, for the most part, in straight, parallel lines, and profusely inlaid with granules, as in fig. 6. Soon after this process has begun, vessels appear in the new product, either as a result of the canalization of branched cells, or as an extension from the neighboring structures, the latter being by far the more common source of the supply. The walls of the vessels are, at first, very frail and yielding, so that the least pressure is sufficient to rupture them and cause extravasation of their contents. Gradually, however, as they grow older, they become better qualified for the discharge of their functions, and in time acquire all the properties of the natural vessels. When fully developed, they can easily be discovered with the naked eye, and readily admit fine injecting matter. The veins are usually disproportionately large to the arteries, but this defect also ultimately disappears. Nerves and absorbents likewise exist, but whether they are supplied by the surrounding tissues, or by the inherent powers of the effused matter, is undetermined.

The arrangement of the newly-formed vessels is represented in the annexed sketches. Fig. 9 is a portion of plasma attached by a narrow neck to the peritoneal coat of an

inflamed intestine. The vessels have a ramiform disposition, and freely anastomose with each other. Fig. 10 is a piece of false membrane of the pleura. The vessels are large, numerous, and further advanced than in the other sketch.
Fig. 6.   Fig. 7.   Fig. 8.
Figs. 6 and 7, from Bennett, show Nuclei and Cells developing themselves into Fibres ; while Fig. 8 exhibits a Perfect Fibrous Tissue.

When the process of organization is unusually rapid, the new vessels, in consequence of their very tender and brittle condition, occasionally give way, either under the influence of external violence, or the force with which the blood is impelled into them by the heart's action. Such an occurrence may be productive of considerable hemorrhage.

Fig. 9.   Fig. 10.

Newly-formed Vessels in Plastic Lymph.   Vessels in False Membrane of the Pleura.
The organization of plasma is sometimes completely prevented by the contact of extraneous matter, as feces or urine. Hence, we seldom meet with a false membrane in the bowel and bladder. The very moment the plasma is poured out it is devitalized and converted into an effete substance. The state of the blood and solids also exercises an important influence upon the process ; the more impoverished and exhausted these are, the less likely will the effused matter be to form cells and nuclei, vessels, nerves, and absorbents.

Plasma is susceptible of absorption both in its fluid state and after it has been changed into connective tissue. This, however, does not occur, at least not to any considerable extent, during the height of the inflammation by which it has been produced ; on the contrary, there must always be a marked reduction of the morbid action before the absorbent vessels can be induced to take hold of it ; but this point having once been attained, the process often goes on very rapidly, as is witnessed in fractures, dislocations, wounds, and other injuries, in which the swelling, chiefly caused by fibrinous deposits, occasionally completely vanishes in a few days. The absorption will necessarily be more difficult when the plasma has become organized, when, in fact, it often effectually resists all the efforts that can be employed to get rid of it. The opaque spot on the cornea, for example, often remains despite the most protracted treatment. It is probable that plasma, before it can undergo absorption, even in its liquid state, is broken up and dissolved in the fluids of the affected parts, being thus brought more readily under the influence of the vessels. In fig. 11 the fibrous matter is undergoing absorption, some parts of the layer being completely removed, while others are becoming softened and attenuated.

Moreover, this substance is liable to various kinds of degeneration, both in its early and in its more matured stages. When recently effused, it may be converted into pus, especially if it be aplastic and exposed to the air ; and it then also frequently becomes hard, dry, shrivelled, devitalized, and effete. It likewise undergoes the fatty transforma-

tion, both before and after vascularization, as exhibited in Fig. 12 ; and, lastly, it is occasionally infiltrated with pigmentary matter.

Finally, organized plasma forms the basis of what are called the analogous tissues, and may, therefore, like the original structures with which it is in contact, become the seat of inflammation, sarcoma, tubercle, and other formations.

Uses of Plastic Matter.—The great value of this substance is strikingly illustrated in numerous diseases, injuries, and operations.   As a reparative agent, as a living animal glue, as it may very properly be termed, it is impossible to overestimate its importance. If it were not for its interposition, no wound, sore, or ulcer, however insignificant, could ever heal.   In the treatment of an incised wound the duty of the surgeon is strictly mechanical, consisting simply in the approximation of the raw surfaces, and in their retention by suitable dressings.   Nature does the rest by the effusion and organization of plasma, generally well and quickly, provided the parts are kept perfectly cool and quiet. Very little inflammation is required.   The great danger is in overaction, thereby thwarting the efforts at repair.   Under proper management the wound generally heals in a few days, the bond of union becoming hourly more and more firm by the gradual conversion of the plasma into connective tissue, of which, however, very little ordinarily remains when the process is perfected.

Parts completely severed, and immediately replaced, will often, if judiciously managed, reunite, and be nearly, if not quite, as useful as before.   Numerous well-authenticated cases are upon record of bits of fingers, the nose, and the ear having been successfully treated in this wise.

It was upon a knowledge of the peculiar plastic properties of lymph that Tagliacozzio founded his world-renowned operation, now universally known by his name, of repairing mutilated noses, lips, and ears.   His attention was originally directed to the subject by watching the effects of the grafting of trees ; he observed that the transplanted portion not only contracted firm adhesions in its new situation, but that it generally grew with great vigor, and ere long produced most excellent fruit, altogether superior to, and different from, that of the parent stock.   Possessed of a profoundly inventive genius, he was led to believe that a similar operation might be performed upon man, and it was not long before he put his reasoning to the test of experiment.   His success was so complete that he became the great rhinoplastic surgeon of his day.   His method consisted, first, in raising a suitable flap of integument from the arm ; secondly, in thoroughly paring the mutilated organ ; and lastly, in sewing the raw edges accurately together, care being afterwards taken to put the parts in the closest relation until they were firmly and inseparably united.   The Indian method, as it is termed, differs from that of Tagliacozzio mainly in this, that the flap of skin is generally borrowed from the immediate vicinity of the deformed organ, its pedicle being twisted upon itself in such a manner as not to interfere injuriously with its circulation.

Some very curious experiments, illustrative of the surgical uses of this substance, were performed towards the middle of the last century by Du Hamel ; one of these experiments consisted in ingrafting the spur of a cock upon the comb of the same bird, where it speedily contracted adhesions, and gradually attained a large size.   Hunter, who repeated the experiments of the Dutch physiologist, went a step further, transplanting the

testis of a cock into the abdomen of a hen, where the union became so perfect that he could readily pass injecting matter from the vessels of the one into those of the other. The fact that a healthy tooth, extracted by mistake, will, if immediately replaced in its socket, speedily reunite, and ultimately regain its original hold, has long been familiar to dentists. Hunter found that if a fresh human tooth be inserted into the comb of a cock, it will soon become firmly fixed in its new situation, vessels extending up into the cavity of the fang, so as to establish an active circulation between the two bodies.

Curious and instructive as these experiments are, they hardly equal, in point of interest, many of those that have been performed by the modern surgeon upon the human subject for the relief of mutilated structures. One of the most recent additions to our knowledge is the transplantation of bits of skin for the cure of wounds and ulcers, suggested by Reverdin, and so successfully employed in numerous instances both in Europe and in this country.

The good effects of plasma are exhibited in various other processes, as in the suppression of hemorrhage, and the radical cure of hernia. In the former, the patient would inevitably bleed to death if it were not for the agency of this substance in sealing the mouth of the vessel by attaching the internal clot firmly to its surface. In hernia a radical cure can only be effected through the intervention of plastic matter, thrown out as a consequence either of the pressure of a well-adjusted truss, or of the injection of some irritating fluid, causing inflammatory action of the parts around.

Plastic matter is often useful in circumscribing morbid action, and in inclosing foreign bodies. In abscess a wall of this substance is generally formed around the pus, effectually preventing its diffusion among the surrounding tissues. Occasionally the fluid is inclosed by a distinct membrane, derived from the fibrin of the blood, and possessed of a high degree of organization. In carbuncle and erysipelas the matter is usually of an aplastic nature, and therefore unable to prevent the extension of the disease. Balls, needles, pins, and various other foreign bodies are occasionally surrounded by a cyst, and, in consequence, often remain harmless tenants of the body for many years.

Plasma may be of service in obviating accidents. Thus, in abscess of the lung, if it were not for the intervention of fibrin, the matter would often break into the chest, and rapidly destroy life. As the disease advances, the pulmonary pleura becomes inflamed and pours out lymph, which thus serves as a bond of union between this membrane and the costal pleura; so that by the time the matter reaches the surface an effectual barrier is opposed to its effusion, and the consequence is that it generally discharges itself through a contiguous bronchial tube. A similar occurrence takes place in abscess of the liver in relation to the peritoneum and the intestinal tube. In typhoid fever the glands of Peyer are often perforated, and yet the contents of the bowel seldom escape into the abdominal cavity, simply because, as the disease progresses, the contiguous serous structures are firmly glued together by plasma.

Finally, lymph is of use in obliterating serous cavities. In the radical cure of hydrocele, a disease of the vaginal tunic of the testicle, an operation is performed for the purpose of provoking a deposit of fibrin, barely sufficient to cover the opposing surfaces, and to insure their permanent agglutination. Serous cysts are treated upon similar principles; and modern surgery has been emboldened to inject even some of the movable joints, the abdomen, and ovarian tumors with irritating fluids, for the radical cure of dropsical diseases of these parts.

Injurious Effects of Plastic Matter.—Lymph is capable of producing injurious effects as well as beneficial; nature's operations cannot always be controlled by art, and it is, therefore, not surprising that she should often overleap the bounds of discretion when engaged in depleting inflamed structures by the effusion of plastic matter. Immense mischief is frequently done in this manner within a few hours after the commencement of the morbid action; mischief which it may require months of the most judicious and persevering efforts of the surgeon to eradicate.

Among the more common and obvious effects of this description are the following: 1. Mechanical obstruction of the natural outlets of the body. 2. Change of structure by interstitial deposits. 3. Abnormal adhesions. 4. Strangulation. 5. Loss of transparency. 6. Induration and enlargement.

a. An example of mechanical obstruction from a deposit of lymph is afforded by what occurs in the windpipe in plastic croup, the principal anatomical character of which is the formation of a false membrane, which often moulds itself accurately to the shape of the tube, and which, especially if it extend high up into the larynx, may cause suffocation by impeding the entrance of air into the lungs. In rare cases the membrane is detached

and expectorated; but generally it remains despite our remedies, and speedily destroys the patient, even tracheotomy seldom averting death.

In some of the mucous canals this matter is poured out beneath the lining membrane instead of upon its free surface, where, becoming organized, it leads to permanent contraction of the tube. It is in this manner that stricture is formed; when the case is a very bad one, lymph may also be effused into the substance of the lining membrane, and even upon its free surface, as, for example, in what is called the bridle-stricture of the urethra.

3. Change of structure from interstitial deposit of lymph occurs in almost all cases of inflammation, however slight or however situated. In pneumonitis, it closes up the air-cells and minute bronchial tubes, as well as the cells of the connective tissue, producing what is called hepatization of the lungs. Opacity of the cornea, acting obstructingly to the rays of light, is the invariable result of a deposit of plastic matter either beneath its conjunctival covering or in its interlamellar structure.

γ. All abnormal adhesions are effected by this substance, and are necessarily more or less prejudicial. In the thoracic cavity, they confine and restrain the movements of the heart and lungs; in the abdomen, they often become a source of internal strangulation; in the mucous outlets, as in the vagina and uterus, they may produce complete occlusion of their orifices; and in the vessels, especially the arteries, they have been known to induce obliteration of the largest trunks. Abnormal adhesions between the bowel and the sac in hernia are sometimes a cause of its irreducibility.

Great mischief is often done by the lymph that is effused within a joint. The matter, if not promptly removed by the absorbents, is organized and converted into an adventitious structure, which, undergoing various transformations, at length assumes the properties of the osseous tissue, and effectually destroys the motions of the articulation. The case, in fact, is one of bony ankylosis, which it is often difficult, if indeed not impossible, to cure.

δ. When this substance is arranged in the form of a cord or band, it may act as a compressing agent, by arresting the circulation, and thus give rise to all the symptoms of fatal obstruction. A band or cord of lymph, for example, extending from one organ to another, may as effectually strangulate the bowel as when the tube is girted by the rings of a hernia at one of the natural outlets of the abdomen. Dr. Montgomery, of Dublin, has shown that the amputations of the limbs which occasionally occur spontaneously during utero-gestation are due to the constriction caused by cords of this kind accidentally thrown around the affected member, and acting on the principle of a gradually tightened ligature. The constant tendency of such bands to contract affords a ready explanation of an event which, until recently, was universally regarded as a result of gangrene.

ε. Loss of transparency in structures that are naturally transparent, as the cornea, or translucent, as the serous membranes, is a common consequence of a deposit of plasma. This has been supposed by some to be due, in part at least, to a change in the nutrition of the affected tissues; but, in general, it will be found to depend solely upon the presence of inflammatory material.

ζ. Among the more frequent evils of plastic deposits are induration and enlargement, or hardening and thickening of the affected organs and tissues. Such occurrences are generally exceedingly annoying, often severely taxing the patience of the sufferer and the skill of the professional attendant. They are the direct result of interstitial effusions, which often manifest an early tendency to organization and transformation, and which none but the most determined perseverance in the use of remedies can ultimately overcome. The stiff and thickened joint, the indurated and enlarged testicle, the hypertrophied spleen, liver, and lymphatic gland, the hardened and enlarged tonsil, so frequently seen in practice, are sad illustrations of the truth of this statement.

When lymph is effused upon an open surface, as a wound or an ulcer, its appearance may generally be taken as a true index of the precise character of the action that is going on in the affected part, as to whether that action is healthy or unhealthy; and it is, therefore, capable of affording valuable therapeutic indications. When it has the requisite degree of vitality, it is promptly converted into healthy granulations and new tissue; whereas, when the reverse is the case, it rapidly perishes, and is finally thrown off as an effete substance or as a species of slough, the surface beneath exhibiting an irritable, inflamed, phagedenic, or gangrenous aspect, and discharging a thin, serous, or bloody fluid, more or less fetid, and entirely destitute of the properties of laudable pus. This local action of the part is generally associated with a depraved, vitiated, scorbutic, or typhoid state of the system, and is liable to run into the very worst forms of pyemia and erysipelas, especially during the prevalence of epidemics, among the inmates of crowded, ill-venti-

lated hospitals, and other establishments for the accommodation of the sick and wounded. Under such circumstances the lymph is nearly always aplastic, so much so, indeed, that the patient may be said to be laboring under a veritable aplastic diathesis.

TREATMENT.—The treatment of lymphization is conducted upon general antiphlogistic principles ; undue action is repressed, and the absorption of effused matter promoted. To accomplish the first of these objects, the ordinary local and constitutional measures are employed ; for the second, sorbefacients are necessary, as mercury and iodide of potassium internally, and the tincture of iodine, liniments, and embrocations externally. In the acute stage of the disease, while secretion is still active, purgatives and antimonials, with the judicious exhibition of calomel, constitute the chief means of relief ; but, the tendency to deposit having ceased, their use is dispensed with, all except the mercury, which is now given in minute doses, and with a view strictly to its alterative effect ; it is often carried to slight ptyalism, the mouth and gums being maintained in a tender condition for, perhaps, several weeks consecutively ; or, with an occasional interval, for even a much longer period. In the latter event, the bichloride frequently, if not generally, forms a valuable substitute for the calomel ; less likely to act hurtfully, and yet, at the same time, very effectually stimulating the absorbents. In such cases, too, small doses of tartar emetic often produce a most salutary influence, its action being hardly inferior to that of mercury itself, with which it may frequently be advantageously combined. When the inflammation has measurably subsided, its products, especially the serous and plastic, are generally easily disposed of by chloride of ammonium, or iodide of potassium, administered in doses varying from three to twenty grains, thrice in the twenty-four hours ; strict attention being meanwhile paid to the diet and bowels. When the case is obstinate, an occasional mercurial constitutes a valuable addition.

Among the more beneficial topical means are, the dilute tincture of iodine, applied twice in the twenty-four hours ; inunctions with mercurial and other unguents, particularly t .at of the iodide of lead ; stimulating embrocations ; and steady, uniform support with the bandage. Various kinds of plasters, as the common mercurial, the compound galbanum, and others of a kindred nature, are also frequently serviceable. Washing the part well, when accessible, twice a day with hot water and Castile soap, followed by dry friction, often does more good than anything else. In some cases, again, cold, especially in the form of the douche, acts very beneficially, affording relief when other treatment fails. In the joints passive motion must be carefully performed, at first once, and then twice a day, to prevent ankylosis from the organization of the fibrinous bands which are so liable to form during the progress of synovitis.

When the object is simply to assist nature in her efforts to repair an injury, as a wound or fracture, care should be taken, on the one hand, that the attendant action is not too low, and, on the other, that it does not transcend the fibrinizing limits. By overofficiousness the system may be so exhausted as to render it impossible for the part to furnish an adequate amount of lymph, and a similar condition is often induced by debility, the result of previous disease, intemperance, or imperfect nutrition from want of proper food. Whatever the cause may be, it should be promptly counteracted by the use of tonics, especially quinine and iron, alcoholic stimulants, and other invigorating measures, to supply the blood with the requisite material for the deposition of fibrin ; all enfeebling topical applications being at the same time discontinued. Overaction, on the contrary, is met by the usual antiphlogistic means, carefully and warily applied, lest harm should arise from the too rapid reduction of the vital powers. The management of the reparative process always demands great judgment and vigilance.

SECT. IV.—SUPPURATION AND ABSCESS.

Suppuration, the process by which pus is formed, is one of the most frequent, as it certainly is one of the most important, of the results, events, or conditions of inflammation. Its presence, as a rule, is denotive of a higher grade of excitement than a mere deposition of serum and plastic matter, which, however, are nearly always associated with it. But it must not be supposed that the reverse of this proposition is true ; for inflammation often exists in a severe degree, with an abundant effusion of the watery and fibrinous elements of the blood, and yet there is not the slightest evidence of suppuration.

It was formerly supposed that suppuration might occur independently of inflammation, an opinion which, doubtless, had its origin in the fact that there are occasionally cases in

which large quantities of pus are thrown off, without any evidence of the ordinary phenomena of inflammation, such, especially, as pain, heat, and discoloration of the structures in which the matter is formed, or any constitutional disorder ; the whole process being apparently conducted as if both the part and system were unconscious of what is going on.   Such cases are by no means infrequent, and yet, if they be carefully investigated, or traced through the various stages of their progress up to the dissection of the affected tissues, the most satisfactory proof will be afforded of their phlogistic nature.   In a cold, strumous, or scrofulous abscess, for example, which has so often served as the basis for this now exploded idea, and the formation of which is sometimes the work of several months, inflammation is just as much concerned in the production of its contents, as in a phlegmonous boil that is developed in three or four days.   The only difference is that in the one the morbid process advances very slowly, indeed almost imperceptibly, while in the other it proceeds very rapidly, and is accompanied by such well-marked symptoms as to render it impossible to mistake their character.

Matter may form without any breach of continuity of the affected parts.   This mode of suppuration is, in fact, very common, not only in the serous cavities, but throughout the greater portion of the mucous system.   It is not, however, confined to these textures.   In the connective tissue, lungs, brain, liver, and other viscera, nothing is more frequent than suppuration without any ulceration whatever in the incipient stages of the morbid action.

Suppuration does not take place equally readily in all the organs and textures.   Of the viscera, those most prone to it are the liver, lungs, and brain ; of the tissues, the connective, cutaneous, mucous, and serous.   In the fibrous, cartilaginous, tendinous, and osseous textures, pus not only forms with difficulty, but is seldom of a thick, consistent character.   Of the mucous system some portions are more liable to suppuration than others.   Thus, it is much more common in the colon than in the stomach or ileum, in the vagina than in the uterus, in the urethra than in the urinary bladder, in the nose than in the mouth, in the fauces than in the œsophagus, in the bronchia than in the larynx.   So, likewise, in the serous system, suppuration is more frequent in some situations than in others, as for example, in the pleura, the vaginal tunic of the testicle, and the lining membrane of the larger joints.   In the subcutaneous connective tissue, pus forms most rapidly in parts remote from the heart.   The bloodvessels do not often suppurate, except when wounded ; and the same, so far as can be ascertained, is the case with the absorbents.   The lymphatic glands, however, suffer very frequently, especially those of the axilla, groin, neck, and base of the lower jaw, particularly in persons of a scrofulous taint.   Nervous tissue seldom suppurates ; muscular still more rarely.   From all these facts we may deduce the axiom that those structures are most prone to form matter which contain the largest amount of loose connective substance, and, conversely, that those which possess this tissue sparingly always suppurate with difficulty, requiring, generally, a much longer period, and elaborating a less perfect fluid.

The period at which suppuration occurs after the establishment of inflammation varies, on an average, from twenty-four hours to three or four days, depending upon the nature and situation of the affected tissues, the intensity of the morbid action, and also, in a very material manner, upon the condition of the system, and the character of the exciting cause.   Mucous membranes, especially if exposed to the air, generally suppurate very readily, having, seemingly, a predisposition to take on this kind of action ; serous membranes, on the contrary, as they are arranged in the form of shut sacs, do not feel the stimulus of the atmosphere, and, therefore, suppurate with difficulty ; another reason, doubtless, is the fact that such structures, when irritated, are naturally inclined to furnish lymph rather than pus, their organization peculiarly fitting them for that office.   The same difference exists between the veins and arteries, and it is practically fortunate that it does ; otherwise the danger of wounds, whether the result of accident or design, requiring ligation of the principal arteries, would be much greater than it is.   In some of the internal viscera, as the brain and liver, pus occasionally forms with great rapidity, as is seen in cases of injuries of these organs.   Matter, other things being equal, forms most readily when the inflammation is very intense.   A wound in an unhealthy or intemperate person is more likely to run speedily into suppuration than a similar one in an individual of sound constitution and regular habits.   A phlegmonous boil usually pours out pus in from twenty-four to thirty-six hours, whereas a chancroid does not furnish any until about the beginning of the fourth day.   In variola, the suppurative process is seldom fully established before the ninth day.

Exposure of an inflamed surface to the air greatly promotes suppurative action, and

is, therefore, directly hostile to adhesion. The more nicely the edges of a wound are approximated, the greater, other things being equal, will be the probability of speedy and permanent reunion, and conversely. Serous membranes, as already stated, have naturally a disposition, when inflamed, to pour out lymph, and to contract adhesions; but whenever they lose the character of closed sacs, as they necessarily do when they are accidentally opened, the morbid action, consequent upon the injury, is certain to be followed by the formation of pus, especially if the air have free access to them for any length of time.

When suppuration is fully established, it is impossible to predict when it may terminate. In many situations, as, for example, the bowels and the bronchial tubes, it occasionally lasts for years, the discharge literally usurping the place of the natural secretions.

Suppuration, when very profuse, as in a lacerated wound, an inflamed joint, or a large, irritable ulcer, leads to rapid exhaustion by the abstraction of the more important elements of the blood, and by the induction of hectic fever, pyemia, or purulent infection, generally attended by severe rigors and copious sweats, rapidly draining the system. The appearance of thick, yellow, cream-like pus, under such circumstances, is always hailed by the surgeon as a gratifying omen, indicating, as it does, a decided improvement both in the part and system. Pus serves as a protective to granulating surfaces, preserving moisture and promoting growth; assists in detaching foreign bodies impacted in the soft structures and is probably instrumental, at least at times, in eliminating noxious matter from the blood, or so changing its character as to render it harmless.

Pus, the product of suppuration, originally appears in the form of distinct globules, dispersed through the affected structures, where they may be easily recognized by their pale yellowish color. As the particles increase in number, they gradually become confluent by the removal of the diseased tissues, the matter being thus collected into an abscess.

The symptoms which characterize the suppurative process will claim special attention under the head of abscesses. Here it will suffice to observe, in general terms, that they are such as denote the existence of ordinary inflammation, with an increase, more or less considerable, of the local and constitutional disturbance.

Pure pus, such, for example, as is found in a well-matured phlegmonous abscess, is an opaque, homogeneous fluid, of a yellowish-white color verging on greenish, of a sweetish taste, without any particular odor, of a cream-like consistence, slightly viscid, and of an average specific gravity of 1030 to 1033. It has a faint alkaline reaction, is imperfectly soluble in water, does not readily putrefy, and is coagulated by heat, acids, and chloride of ammonium. Freezing destroys its normal properties.

The specific gravity of pus is liable to considerable variation, depending mainly upon the quantity of its solid ingredients and the density of the pus-liquor. Thus, in seven examinations of this fluid, taken from abscesses in different situations—as the thigh, arm, axilla, back, pleura, and the lung in pulmonary phthisis—Dr. John Davy found the specific gravity as low in one as 1021, and in another as high as 1042.

Pus essentially consists of the elements of the blood, in an altered state, water constituting about eighty-five per cent., the remainder being made up of albumen, fatty matter, osmazone, and salts, as chloride of sodium, and phosphate of calcium and magnesium. Lehmann, who has carefully examined this fluid, found the quantity of fatty matter to vary from 2 to 6 per cent., and the quantity of albumen in the serum from 1–2 to 3–7 per cent. Casein and hematin do not exist in normal pus. A peculiar principle, termed pyine, has been detected in it by Güterbock, supposed by some to be an oxide of protein, by others a form of fibrin. It is soluble in water, but insoluble in alcohol. Recent examinations have shown myosin, paraglobulin, protozen, leucin, and tyrosin to be constant constituents. Pyocyanine, the substance which imparts the bluish or greenish color to the contents of certain abscesses, and to the discharges of certain ulcers, is occasionally present. Pus of an orange color is sometimes met with, but all attempts to trace its origin, or to decipher its significance, have thus far failed.

Pus is composed of numerous corpuscles, suspended in a thin, transparent fluid, called pus-liquor. These little bodies, known as pus corpuscles, are spherical, finely granular masses of germinal matter or protoplasm from the $\frac{1}{2000}$ to the $\frac{1}{3000}$ of an inch in diameter, and identical with lymph and colorless blood corpuscles. They are not vesicular in structure, for what was formerly considered to be a distinct cell-wall, is now known to be simply a peripheral, limiting layer of non-germinal or formed material. They are provided with nuclei, which are rendered visible on the addition of water or acetic acid, and are deeply stained by ammoniacal solutions of carmine. Some contain one well defined nucleus, others two, three, or more small nuclear bodies, their size depending upon

their number.   Fig. 13, from Rindfleisch, exhibits pus corpuscles in their different forms :
a represents globules containing a single, large nucleus, from the pus of a healthy, granu-
lating sore ; at *b* and *c* are seen cells from an abscess, before
and after the action of acetic acid ; broken-down globules,
from the pus of carious bone, are delineated at *d* ; while at
e are shown the forms which the living cells assume, by vir-
tue of their softness and elasticity, in their amœboid move-
ments.

Fig. 13.

Various Appearances of Pus
Corpuscles.

The pus corpuscles float in the pus-liquor, and are inter-
mixed with various solid elements, as granules, shreds of
fibrin, epithelial matter, and also, at times, with small
homogeneous, non-nucleated corpuscles, termed pyoid.

Pus is liable to be modified in its properties by the pres-
ence of extraneous substances, as grumous blood, fibrin,
cholesterine, and the debris of the organs and textures in which it is formed.   In com-
mon phlegmon, it often contains shreds of connective tissue, of a dirty grayish color, not
unlike wet tow.   The brownish matter found in certain abscesses of the liver probably
derives its color and consistence from the intermixture of softened, disintegrated, hepatic
parenchyma.   In suppuration of the different glands, the pus is not unfrequently mingled
with the product of their peculiar secretions, as urine in the kidney, bile in the liver,
milk in the mamma, and semen in the testis.   Purulent matter is sometimes very fetid,
apparently from the extrication of sulphuretted hydrogen.

The different varieties of pus have received different names.   When the fluid is of a
whitish, or pale yellowish color, creamy in consistence, and composed of numerous globules,
it is said to be *healthy*, pure, or laudable, in reference to the process by which it is pro-
duced, this being of a healthy, sanative, or restorative nature.   It is usually met with in
suppurating wounds, in healing ulcers, and in phlegmonous abscesses.

Sanious, serous, ichorous, or sanguinolent pus is thin, almost transparent, of a yellowish,
amber, or reddish color, and generally so acrid as to erode the parts with which it comes
in contact.   It is a product of unhealthy inflammation, and is principally observed in caries
of the bones, irritable ulcers, and open carcinoma.   This variety of pus is often intermixed
with grumous blood, flakes of fibrin, and the debris of the affected tissues.   The thin, sani-
ous pus furnished in abscess, ulceration, and necrosis of the osseous tissue, not unfrequently
contains a considerable quantity of phosphate of lime.

Fibrinous pus consists of common pus in combination with plasma.   It is of a whitish,
grayish, or cineritious color, and of a semiliquid, concrete, or lardaceous consistence.
Under the microscope, it displays the globules of healthy pus, with numerous other cells
and fibres, of irregular shape.   It is usually found in the joints, in the splanchnic cavities,
in metastatic abscesses, and in carbuncular inflammation.   Its presence denotes a high
degree of morbid action.

Scrofulous pus is chiefly met with in pulmonary caverns, cold abscesses, scrofulous dis-
ease of the joints, and chronic inflammation of the lymphatic glands.   After standing a
while, it usually separates into two parts, of which one is thick, straw-colored, and inodor-
ous ; the other, which rests on the surface, is oily in appearance, thin, ropy, and mixed
with small, opaque, curdy flakes.   When scrofulous pus is long retained, it may acquire a
disagreeable, nauseous smell, not unlike the pollen of the chestnut ; at other times it is
excessively fetid.   The attendant action is usually very languid.   The term curdy is often
applied to this variety of pus.

Gummy pus, as it is termed, is a product of syphilitic affections of the bones, muscles,
connective tissue, and internal organs.   In its appearance it bears a strong resemblance
to a thin solution of isinglass, arrowroot, or gum arabic, is of a pale whitish color, more
or less ropy in consistence, and in great degree destitute of the properties of ordinary pus.
It is composed mainly of albumen, and contains only a few well-formed pus corpuscles :
oil globules and fatty matter are usually present in it.

There is a variety of pus to which, from its admixture with mucus, the term *muco-pu-*
rulent is applied.   It is usually a product of a high degree of inflammation of the various
outlets of the body, particularly of the nose, eye, bronchial tubes, and genito-urinary
apparatus.   The mucus supplied by these surfaces in the healthy state is composed of a
transparent fluid, and of abraded epithelial cells, flat, and irregularly sided, with a central
nucleus.   In addition to these, the microscope detects numerous granular masses and
spherical globules, similar to those of pus, suspended in a viscid, transparent, ductile fluid.
Under inflammation, the epithelial cells are cast off so quickly that they do not have time to be flattened out, and the globules are not only greatly augmented in number, but they acquire somewhat the character of those of pus.

Finally, what is called *puriform* matter, is, as the name implies, not genuine pus, but an imperfect liquid bearing some resemblance to it. It occurs chiefly in bad forms of inflammation, as erysipelas, carbuncle, and pyemia, and consists essentially of broken-down lymph and shreds of tissue, interspersed with fatty substance, granules, abortive cells, and a few globules, smaller than those of pus, and not affording the usual reaction under acetic acid. The puriform matter, so abundantly thrown off in inflammation of the serous membranes, is generally nothing but turbid serum.

Certain kinds of pus, as those, for example, of smallpox, varioloid, farcinia, gonorrhœa, and venereal ulcers, are *contagious*. In what particular element of the fluid the virus or specific secretion is contained, or whether it exists as an entity, is undetermined. The vitality of the organ by which it is elaborated is not necessary for the preservation of its peculiar effects. Once formed, it becomes independent of its source, and retains, for a considerable period, the power of contaminating the parts to which it is applied, producing a disease of the same character. Various chemical reagents, however, as the alkalies and acids, effectually neutralize, if they do not completely destroy, its specific properties. The pus of a chancroid often contains animalcules, particularly the vibrio lineola.

Pus is a substance that is easily altered in its properties, the causes which mainly contribute to this result being its age, or the length of time during which it is retained in the body, and the contact of various fluids, especially air, gas, and water. The globules of the pus of an old abscess always contain fine fatty granules, generally from five to ten in number, which, when the development is unusually perfect, present a large, swollen appearance. The caseous transformation is observed chiefly in old scrofulous abscesses, the pus-liquor of which is absorbed, while the pus globules, assuming an angular configuration, shrink, atrophy, and form, by their agglomeration, a dryish caseous mass, of a whitish or slightly yellowish color. In abscesses of the cancellous structure of the bones, especially in those communicating with the joints, the fluid is generally very thin and watery, and not unfrequently contains lactic acid, under the influence of which the pus cells are distended, the protoplasm dissolved, and the nuclei set free. In suppuration of the joints of the fingers in gouty persons the fluid usually contains a large quantity of urate of soda. The pus globules always experience great alterations in their size and shape when pus contains an unusual quantity of water. The presence of gas in pus has a tendency to decompose it, to render it fetid, and to change its color. Pigmentary infiltration of the pus globules occurs whenever the suppuration is attended with any considerable effusion of blood.

The distinction between pus and mucus is of practical importance. The microscope is the most certain means of discrimination; but, in its absence, other measures may be resorted to. Pus sinks in water; mucus floats. A glairy, viscid, gelatinous mass is formed by the addition to pus of about half its quantity of the officinal solution of potassa, no such effect resulting from the action of the alkali on mucus, which becomes more fluid and limpid. The serum of pus is highly albuminous; mucus is not. Mucus treated with acetic acid coagulates into a thin, membranous substance; pus does not. Under the application of ether, mucus yields the merest trace of fat, while pus always furnishes this material in considerable quantity. Pus diffused through blood can only be satisfactorily detected with the microscope, but in many cases the examination is very difficult on account of the very close resemblance of the globules of the two fluids to one another.

The differences between pus and milk, as in mammary abscesses, are generally easily distinguished by the relative size of the globules, those of the former being a good deal larger than those of the latter fluid. Purulent urine always contains albumen, and exhibits the characteristic pus globules. Softened and broken-down fibrin, as in clots in the bloodvessels, connective tissue, old aneurisms, and the splanchnic cavities, sometimes bears a considerable resemblance to pus, but differs from it in being destitute of exudation cells. Softened atheromatous matter is distinguished by the presence of cholesterine and the absence of pus corpuscles.

By far the most ready, delicate, and trustworthy differential test of pus, however, is the color test, discovered by Dr. John Day, of Victoria. It is founded on the property possessed by oxygenated tincture of guaiacum of turning a clear blue color when brought in contact with pus, no such effect being produced on mucus, except on the addition of carbolic acid diluted with alcohol.

Pus was formerly supposed to be a product of broken-down fibrin; but the observations of Virchow, Cohnheim, and other German pathologists, show that pyogenesis is due to the disturbances of the circulation and nutrition of the affected structures, through which the activity of local protoplasmic masses is increased, as evinced by their enormous multiplication. It has been demonstrated by Virchow that, under the influence of the assimilation of an excess of blood-liquor, which has escaped from the dilated vessels at the focus of the inflammation, the connective-tissue corpuscles proliferate and assume the characters of pus globules. This theory of the formation of pus, however, is too exclusive, and has been placed in doubt by the discovery of Cohnheim, who has shown by a series of well-contrived experiments that pus is in a great degree the product of the colorless blood corpuscles, which have wandered out of the vessels into the tissues. The results of these experiments have been confirmed by the researches of Koster, Vulpian, and other observers, and they carry the mind back to the days of Gendrin, who, in 1824, in his great work on the Anatomical History of Inflammation, enunciated almost precisely similar views, based upon his own investigations. It has, moreover, been demonstrated that other cell elements enter into the formation of pus, as, for example, those of the cornea, muscles, glands, mucous and serous membranes, which by their germination aid in the process. These points have been fully discussed in studying the intimate nature of inflammation, and need only be thus briefly referred to here. They, however, clearly point to the fact that pus is a fluid inflammatory new formation, due to the accumulation of young cells, which are derived partly from the blood, and partly from the cell elements normal to the tissue or organ affected.

Pus corpuscles are originally alive, and in a state of active amoeboid movement, proliferating and sending out offshoots which form new corpuscles. Their transition from lymph and blood corpuscles may in many cases be distinctly traced with the aid of a magnifying glass; but how, or in what manner, they obtain their peculiar color and other physical properties, is undetermined. The probability is that the process is partly of a vital, partly of a chemical nature. All that is certainly known is that the pus corpuscles, in their size, shape, and structure, closely resemble lymph or colorless blood corpuscles, and that the fluid in which they are suspended always contains more or less oily matter, which, formed during their metamorphosis, constitutes one of its characteristic attributes.

Pus is susceptible of absorption, probably in all its varieties, as well as in almost every locality. Of this fact satisfactory proof is afforded by what occurs in abscesses in the different external parts of the body; and it is, therefore, analogically reasonable to infer that it may also take place in the internal organs and cavities. Great doubt has been expressed by some pathologists respecting the possibility of pus being taken up in this manner, on the ground, chiefly, that the accumulations which occasionally disappear, both spontaneously and under treatment, are really not abscesses, but collections of plastic matter. Every surgeon of experience, however, knows that pus, or puriform fluid, is sometimes removed by the agency of the absorbents, after its existence has been satisfactorily tested by the exploring needle. Particular remedies are often employed for the attainment of this object, and our efforts are certainly not unfrequently crowned with success, although probably not so often as is generally supposed.

When pus disappears spontaneously, it is highly probable that the more fluid elements enter the system readily, and without any previous change; indeed, recent observation has shown that even the pus corpuscles may do this, although it is reasonable to suppose that, as a rule, the absorbent vessels do not admit them unless they have been more or less disintegrated and broken down. Whether the fatty matter remains, or whether it, also, is removed, has not been determined. How pus is disposed of, after it has reached the circulation, is likewise unknown; the most reasonable conclusion is that it undergoes oxidation, and that it is excreted by the liver and kidneys, if not, also, by some of the other emunctories.

ABSCESSES.

An abscess is a circumscribed cavity of abnormal formation, containing pus. When the matter is poured into a natural cavity, as the chest, or into a joint, the collection constitutes what is called a purulent effusion. An abscess may be superficial or deep, acute or chronic, common or specific. It is said to be superficial when it lies immediately beneath the common integuments or in the connective tissue among the superficial muscles. The word deep, on the contrary, is used when the matter is lodged in an internal organ,

in a bone, or among muscles. The terms acute and chronic have reference merely to the time occupied in the formation of the abscess. A common abscess is one produced by ordinary inflammation; while the specific abscess is the result of the operation of some particular poison, as the virus of chancroid, smallpox, or glanders. Finally, an abscess is circumscribed, as when it is bounded by plastic matter; or diffused, as when its contents are sent abroad through the connective tissue.

The most natural division of abscesses is into phlegmonous, scrofulous and metastatic, the first being incident to all persons, while the second occurs only in certain classes of individuals, or such as are affected with a strumous taint of the system. The term "metastatic," formerly so much in vogue, is employed to designate those collections of pus which supervene upon severe injuries, operations, and diseases, and might advantageously be abolished, as it is calculated to convey false impressions respecting a form of suppuration which properly comes within the definition of phlegmonous, although, as will be shown by and by, it is generally supposed to have its origin in a septic condition of the blood. It has also been described under the term "multiple," and will claim particular attention under the head of pyemia. It is not easy, in the present state of the science, to assign an appropriate place to the diffuse abscess, as it is often impossible to determine its true character. The specific abscess does not require any special consideration, since, apart from its exciting cause, its mode of formation does not, so far as we are able to comprehend it, differ at all from that of the common phlegmonous abscesses.

Sir James Paget, in 1869, described what he calls the "residual abscess," formed out of the debris of former structures of this kind, often at the distance of many years, from a recurrence of inflammation, especially after the system has become exhausted by the influence of disease or accident. The occurrence is most common in connection with scrofulous abscesses, the walls of which, left in an unsound condition, are very susceptible to fresh attacks of inflammation, the predisposition to disease being augmented, often very greatly, by the retained, withered, half dry, and degenerated pus. Instead of calling such abscesses residual, it would be more appropriate to denominate them "recurrent," as the name is more expressive of their peculiar character.

1. PHLEGMONOUS ABSCESS.

A phlegmonous abscess is one which, running its course with unusual rapidity, is always accompanied by well-marked inflammatory symptoms. The part feels, as the name implies, as if it were on fire, being hot, tender, and exquisitely painful. A tensive, throbbing sensation is usually present, synchronous with the pulse at the wrist, and greatly aggravated by dependent position; it is particularly severe at the focus of the morbid action, and is a valuable diagnostic symptom, as it is generally denotive of suppuration. Its immediate cause, as explained elsewhere, is obstructed circulation, with consequent pressure upon the nerves of the affected structures.

The mode of development of a phlegmonous abscess is an interesting study. In the first place, the matter is obliged to have a receptacle for its accommodation. This is usually furnished by the cells of the connective or areolar tissue of the part; but as the accumulation, at first drop-like, progresses, this substance is destroyed by ulcerative action, or by the action of the absorbents, and a cavity is thus gradually formed, often capable, in the end, of holding an immense quantity of fluid. While the process of deposition is going on, plastic matter is poured out at the periphery of the cavity, gluing up the connective tissue, and thereby forming a kind of boundary line around the pus, which effectually prevents its diffusion among the surrounding structures. No distinct cyst is constructed, for nature has not time for such an enterprise, nor is she at all in need of it, although the occurrence is not impossible even in acute abscesses, especially in one of the liver. The next phenomenon to be observed is the effort which the matter makes to reach the nearest surface, for this is one of the laws of interstitial suppuration. To this end the matter itself is eminently contributary, the pressure which it exerts upon the superimposed parts greatly promoting and expediting the ulcerative action, by the agency of which evacuation is finally attained. Thus, at least three separate and distinct processes are going on during the formation of an abscess; a deposit of pus, an effusion of plasma, and ulcerative absorption. The importance of an effusion of plasma is shown by the fact that, when this substance fails to be poured out, the contents of the abscess are widely diffused among the surrounding structures, committing extensive havoc in the connective tissues, and causing frightful separation of the muscles. These evil effects are often witnessed

in phlegmonous erysipelas, where, from the cacoplastic character of the lymph, the matter occasionally burrows to a great distance, destroying everything within its reach.

The great law which presides over the spontaneous evacuation of abscesses, by which their contents are enabled to reach the nearest surface, is attended with the most fortunate results, for it not only abridges suffering, but saves structure. Thus, in abscess of the liver, a long time would elapse, and an immense amount of pain and constitutional disorder would be caused, if the matter, instead of emptying itself, as it usually does, into an adjoining coil of intestine, were compelled to travel across the walls of the abdomen.

The contents of the phlegmonous abscess usually partake strongly of the nature of well-elaborated pus, being of a whitish, or pale straw color, and of a thick, cream-like consistence, with an abundance of large and well-matured pus corpuscles. Intermixed with them are often flakes of lymph, and the debris of the affected structures. Thus, in abscess of the external parts of the body, it is not uncommon to meet with shreds of connective tissue; in abscess of the liver, with broken-down hepatic substance. Occasionally, again, the pus is blended with the peculiar secretion of the part, as semen in abscess of the testicle, bile in that of the liver, and milk in abscess of the mamma. As a means of diagnosis, a knowledge of these facts is of great practical value, the nature of the adventitious matter often pointing directly to the seat of the disease. Some forms of acute abscess, as those more particularly which follow upon severe accidents and capital operations, and to which the term metastatic is sometimes applied, are made up almost entirely of fibrinous matter, the quantity of pus corpuscles being extremely small. When pus is long retained, the corpuscles may degenerate, breaking down and assuming an amorphous form; while the serum undergoes various chemical changes, often of a putrefactive character, attended, in most cases, with the fatty transformation, and sometimes even with the liberation of calcareous salts.

The contents of certain abscesses are excessively fetid. This is especially true of abscesses around the anus, from the proximity of the pus to the bowel, or from the actual intermixture of fecal matter. The same circumstance occasionally obtains, although generally in a less degree, in abscesses in some other situations, as the tonsils, bones, and lymphatic glands.

An abscess sometimes contains air, the fluid resting upon the top of the matter, as in inflammation of the perineum, about the sacrum, in the ileo-lumbar region, and in front of the abdomen, from a communication with the intestinal tube. A similar occurrence is occasionally witnessed in suppuration of the chest, when the matter contained in that cavity makes an effort to escape externally through one of the intercostal spaces, after an opening has been made into a bronchial tube. In general, the pus, when thus admixed, is excessively fetid, and the abscess is distinctly emphysematous, crepitating under pressure, and often emitting a peculiar gurgling noise.

Phlegmonous abscesses occur at all periods of life, as well as in all classes of individuals. They are occasionally observed within a few weeks after birth, especially in the mamma and in the lymphatic glands of the neck and of the axilla. They may be traumatic, or idiopathic; or, in other words, dependent upon external injury, or constitutional causes, as a depraved condition of the blood, derangement of the digestive organs, or the suppression of some important secretion, as that of the liver, kidney, or uterus. Abscesses of this kind are sometimes of a secondary character, one forming after another, as if there existed a species of pyogenic diathesis. Such an occurrence often proves exceedingly untoward, sadly interfering with recovery, especially during convalescence after protracted fevers and severe injuries.

Although phlegmonous abscesses may form in any part of the body, they are most common in the connective tissue beneath the skin, among the muscles, and around the lymphatic glands, as well as in the substance of these bodies, especially in those of the neck, axilla, and groin. Among the internal organs, those that are most liable to suffer are the liver, lungs, and brain, but even here phlegmonous abscesses, except as a result of external injury, are extremely rare.

The number of abscesses varies from one to a great many, and is generally in an inverse ratio to their size. Two or three large ones occasionally exist simultaneously in different parts of the body; and, on the other hand, the whole surface is sometimes, as in variola, literally covered with small ones. The size of a phlegmonous abscess ranges from that of a mustard-seed up to that of an adult's head.

The symptoms which precede and accompany the formation of a phlegmonous abscess are very variable. In general, they are such as characterize ordinary inflammation. The

part, if open to inspection, is found to be red, hot, swollen, and painful, beating and throbbing synchronously with the left ventricle of the heart. As the matter accumulates, all these symptoms augment in severity, especially if the fluid is bound down by hard, unyielding structures, interfering with its exit or extension. Under opposite circumstances, however, the pain often diminishes, the part feeling relieved almost as soon as the deposition of pus has fairly begun. However this may be, the discoloration of the skin always increases as the matter approaches the surface, and generally assumes a dusky, purple, or livid aspect, particularly at the focus of the abscess. The swelling also augments, and the part often pits on pressure, more or less serum being effused into the subcutaneous connective tissue. The heat is much greater than it is in the surrounding structures, and there is always serious functional disorder.

The morbid action continuing, the centre of the abscess becomes acuminated, and the matter, in surgical language, is said to point. The skin here is not only greatly discolored, but thin and impoverished; and giving way at the most prominent part of the tumor, allows its contents to escape, generally by a small orifice, which is often entirely inadequate to thorough clearance. The period which intervenes between the commencement of the inflammation that leads to the formation of the abscess, and the evacuation of the pus, varies from a few days to several weeks.

When the abscess is small, or situated in a comparatively unimportant part, the constitution may fail to take cognizance of it, but this is the exception rather than the rule; for, in the majority of cases, the system warmly sympathizes with the local trouble, and manifests the interest it feels in it by well-marked inflammatory symptoms. When an abscess is about to form in an internal organ, the patient is seized with rigors, often violent and long continued, alternating with flushes of heat, and generally followed by copious sweats. This frequently happens even when the abscess is of a very trivial size; the importance of the affected structures giving proportionate force to the morbid action. Rigors also generally occur in abscess of the bones and joints, but comparatively seldom when the disease is seated in the subcutaneous connective tissue. An abscess of the ear, parotid gland, tonsil, anus, and perineum is nearly always attended with high constitutional excitement, along with cold, chilly sensations, and what are called muscular pains. If the case is at all severe, delirium will be likely to be present, lasting either until the part is relieved, or until the disease proves fatal. The countenance is generally flushed, the eyes are suffused, and there is often a hectic spot upon the cheek, especially in internal suppuration. The pulse is full, strong, and frequent; the skin hot and dry; the urine scanty, high-colored, and loaded with uric acid. Great thirst and restlessness usually exist. When the abscess is fully formed, the constitutional symptoms, as well, indeed, as the local, often greatly abate, comparative comfort succeeding the violent perturbation. The pulse becomes soft and calm, the surface is bathed with perspiration, the renal secretion increases in quantity and improves in quality, and the patient, grateful for the happy change, falls into a tranquil sleep.

Diagnosis.—Notwithstanding that the symptoms of phlegmonous abscess are usually well marked, cases now and then arise where the diagnosis is so obscure as to cause serious doubt respecting their true character. Indeed, there is probably no department of surgery where so many mistakes are constantly committed as in this. If the records of the science could be thoroughly explored, they would be found to abound in blunders of this kind. As it is, we frequently hear of carcinomatous and sarcomatous tumors, aneurisms, and hernias being opened for abscesses, and life either instantly destroyed, or placed in great ultimate jeopardy, by the operation. Such mistakes, which are more frequent in chronic than in acute abscess, are hardly less injurious to the surgeon than to the poor patient; for they but too certainly ruin his prospects and reputation as a practitioner. Attention to the following circumstances will materially assist in clearing up difficulty: 1. The history of the case; 2. Pointing; 3. Fluctuation; 4. Œdema; 5. The use of the exploring needle.

1. The first object that should claim attention is the *history* of the case. Upon inquiry, it will usually be found that the disease has been of short duration; having commenced with the ordinary symptoms of inflammation, and gradually increased until the suppurative point was attained, the fever being high, and the local distress often extreme. Rigors are looked for if the abscess be deep seated, extensive, or among important structures. The pain is tensive and throbbing, steady and persistent, not intermittent, or severe at one time, and absent at another. The countenance is expressive of great suffering, and, with a surgeon of experience, this symptom alone is sometimes sufficient to establish the diag-

nosis of the case. If the abscess is lodged externally, the swelling is observed to be gravescent, unnaturally hot, excessively tender, intolerant of manipulation, and of a dusky reddish color, especially at its most prominent point. Its career is comparatively brief, a few days, a week, or, at most, a fortnight, sufficing to reach its acme. Then comes the period of dissidence, if the matter is not evacuated; the symptoms abating in severity, the pulse and skin becoming soft, and the pain losing its throbbing character.

2. *Pointing* is a symptom of great importance in the diagnosis of a phlegmonous abscess. It is always most conspicuous where there are, or were, most pain and discoloration, and naturally the least amount of resistance in the overlying structures. The skin looks dusky, purple, or livid, and feels thin and attenuated, as if it were ready to give way, as, in fact, it generally is. A tumor, benign or malignant, may also point, but a careful consideration of the history of the case commonly suffices to show the difference.

3. *Fluctuation* in an abscess necessarily implies the existence of mobility. If the matter lies near the surface, it may readily be displaced on one side, and rendered correspondingly prominent on the opposite. Two methods may be adopted in conducting the examination. In one, alternate pressure is made with the hands or fingers resting upon opposite points of the abscess. As one hand or finger sinks in, the other is elevated, a circumstance clearly denotive of the existence of fluid, although the fluid may not be purulent. The other method consists in percussing the tumor with one hand, the other hand being placed upon the opposite side. If matter be present, an undulatory motion will be imparted, one of the surest signs of suppuration. This method, however, is less delicate than the other, and is applicable only to abscesses of unusual volume. When the matter is seated superficially, its presence may often be detected by passing the finger over the most prominent part of the swelling, when, if there be pus, it will generally sink in a little, in consequence of the skin at that part offering less resistance than at the periphery of the tumor. This method of examination is particularly adapted to small abscesses of the scalp, perineum, tibia, clavicle, fingers, and other superficial portions of the skeleton. Finally, one may often readily satisfy himself of the existence of pus by grasping the suspected swelling, especially if it be very small, with the thumb and forefinger, and then, while the skin is thus stretched or rendered tense, pressing upon the top of the swelling with the index finger of the other hand. Such a mode of exploration is particularly valuable in abscesses of the mamma, testicle, subcutaneous connective tissue, and lymphatic glands of the neck, groin, and axilla.

There are certain parts of the body, which, under the influence of disease and injury, impart a deceptive sensation of fluctuation, as the dorsal surface of the hand, the forearm on a level with the head of the radius, the calf of the leg, the upper and outer aspect of the thigh, and the inner and upper portion of the thigh on a level with the iliac and psoas muscles. A similar condition occasionally exists in the temple. Without a knowledge of these facts, the occurrence of swelling in these regions might readily induce the surgeon to use his bistoury when there is no matter.

4. Valuable information is often afforded by the appearance of the *swelling*. Thus, when the matter is very deep seated, as in an abscess of the thigh, the existence of œdema is nearly always decisive of the nature of the case, especially when it is conjoined with a hard, brawny state of the parts. The fluid cannot, from the manner in which it is bound down, reach the surface, but its presence causes inflammation in the skin and connective tissue, leading to an effusion of serum, and consequently to more or less pitting under the pressure of the finger. In empyema, or purulent collections in the pleura, œdema of the chest, directly over the seat of the fluid, is usually a prominent, and, indeed, in many instances, a characteristic symptom. A puffy, œdematous state of the scalp is often denotive of abscess of the brain and dura mater, in injury of the skull.

Although œdema is in general a valuable sign in suppuration, it occasionally exists in a very high degree without any pus. A few years ago I saw a case of acute sarcoma of the hip and thigh in a young lady of twenty-six, where the quantity of serum in the subcutaneous connective tissue was so great as to produce the most decided fluctuation at various points of the swelling, and yet not a particle of matter followed the insertion of the bistoury.

5. The *affections* most liable to be mistaken for abscess are sarcoma, aneurism, hernia, cystic tumors, and local œdema. From the first of these the history alone of the case will generally suffice for a correct diagnosis. Sarcoma is a chronic affection; a phlegmonous abscess an acute one; the first is attended with little or no pain until ulceration sets in; the latter with a great deal, generally from the moment it begins until it is evacuated.

An abscess may be mistaken for an aneurism, especially if it be seated over a large artery, which communicates to it its impulse. Errors of this kind are most likely to happen when the disease occupies the axilla, neck, groin, or ham, where the tumor receives an impulse from the vessel below. An aneurism of the thoracic aorta, perforating the chest, has occasionally been opened under the supposition of its being an acute abscess. The history of the case, the discoloration of the skin, the imperfect outline of the swelling, and the conical projection on the surface, will generally suffice to differentiate the two affections. An aneurism is usually of slow formation, and does not for a long time manifest any disposition to approach the surface. The disease, moreover, is most common in elderly subjects, whereas abscesses occur at all periods of life.

A strangulated hernia of the groin, abdomen, or upper part of the thigh might be mistaken for an abscess, but such an accident could hardly happen in the hands of an experienced surgeon. The history of the case, the peculiar character of the swelling, and the existence of symptons of strangulation will always be sufficient to clear up any doubt that may arise respecting the nature of the affection.

A serous cyst has occasionally been mistaken for an abscess. Such an error can only occur when the cyst takes on inflammation, attended with discoloration, pain, and fluctuation. The mere site of the tumor is generally sufficient to indicate its true nature, independently of its history.

An acute abscess may be confounded with local œdema of the connective tissue, circumscribed, elevated, puffy, discolored, and more or less painful. The occurrence is most common in the hand and foot, and in the neighborhood of some of the joints, especially in cases accompanied by a considerable effusion of synovial fluid.

6. When, notwithstanding the most thorough scrutiny of the case, the diagnosis remains uncertain, the exploring needle will often decide the question in a moment. The instrument which I usually prefer is an ordinary cataract needle, introduced at the most prominent part of the swelling down to its very centre, and freely rotated upon its axis, in order to condense the walls of the puncture, and thereby facilitate the flow of fluid. If the contents be purulent, the circumstance will be revealed by the appearance of a drop of pus at the orifice; whereas, if the swelling be an aneurism, the discharge will be sanguineous. If the tumor be sarcomatous simply a little blood will probably escape.

Sometimes the diagnosis of a suspected abscess may readily be determined by the aspirator. A small canula having been introduced into the swelling any fluid that may be present rushes at once into the exhausted receiver, and thus reveals the true nature of the affection.

Prognosis.—The prognosis of this disease is influenced by a variety of circumstances, of which the most important are the size, number, and seat of the abscesses, and the age, habits, and constitution of the patient.

A large accumulation of pus is, other things being equal, more dangerous than a small one, because it not only produces more havoc among the tissues, but it exerts more severe pressure upon the surrounding parts, and establishes a greater drain upon the system. Number has an important bearing upon the prognosis. A man may struggle through several abscesses, even when of considerable bulk, but when he is laboring under a great many he will be extremely fortunate if he do not sink under them. Smallpox is always a dangerous disease, chiefly on account of the immense number of abscesses which attend its progress, few patients being able to withstand the irritation and consequent prostration occasioned by their development. The situation of the matter is an object of importance. Thus a small abscess of the perineum may cause fatal retention of urine, as one of the fauces may induce death by compression of the glottis. Importance of structure also influences the issue of the case. An abscess of an internal organ, as the liver, is more dangerous, and more likely to prove fatal, than an abscess of an external part of the body, as a lymphatic gland.

The recovery of a person laboring under phlegmonous abscess is often materially influenced by his age, habits, and state of constitution. Young adults and middle-aged subjects usually get on better than children and very old persons, who often meet such attacks very poorly, making a very feeble show at resistance. The intemperate man has a worse chance than one of good habits, and the man of bad previous health than one who has always had an excellent constitution.

Treatment.—The treatment of phlegmonous abscess is conducted upon general antiphlogistic principles; at first, by depletion, purgatives, antimonials, and the ordinary topical means, to limit deposit and save structure; and afterwards, by the lancet, to pro-

mote evacuation and repair. Sometimes spontaneous removal is permitted, as when the abscess is seated immediately beneath the periosteum as an effect of tertiary syphilis, or when it occupies a lymphatic gland, and has as yet made little progress; favored, if necessary, by the administration of mercury and iodide of potassium, and the application of iodine, blisters, and other sorbefacients. But such cases are exceptional, and do not affect the general rule of practice, which always seeks an early outlet for the pent-up fluid. In some situations we do not even wait for well-marked pointing, much less distinct fluctuation; but assured that matter is present, make an early and free incision, thus abridging suffering and saving structure. The beneficial effects of this practice are strikingly illustrated in abscesses in various parts of the body. Thus, in purulent collections around the anus, an early outlet is indispensable, otherwise the matter will be sure to burrow along the side of the rectum and to perforate its walls, thereby forming an anal fistule. An abscess of the perineum requires prompt interference to prevent retention of urine and the establishment of urethral fistule; of the fingers, lest the matter should travel along the sheaths of the tendons and so produce extensive sloughing and necrosis; of the fauces and tonsils, to prevent suffocation by the pressure of the swelling upon the glottis. The torturing pain of a gum-boil, an abscess of the jaw, is often instantly relieved by an early and free incision. The same procedure in deep-seated abscess of the extremities not only moderates pain and constitutional irritation, but prevents the pus from burrowing among the muscles, and so causing extensive destruction of the connective tissues.

An abscess should be opened early when, from its proximity to a large vessel, there is danger that a communication may be established between them, thus leading to fatal hemorrhage. Such an event will be more particularly liable to occur in delicate children, laboring under the effects of scarlatina, measles, or smallpox, and in elderly subjects worn out by long suffering and an impoverished state of the blood.

Fig. 14.

Mr. Liston's Case. *b*. The External Opening of what was an Abscess *a*. The Ulcerated Communication between the Cyst and the Carotid Artery: the latter has been sliced open. *c*. The Pneumogastric Nerve.

The vessels most subject to this danger are those about the neck. In Mr. Liston's celebrated case, the abscess opened into the common carotid; it was punctured and the patient perished from hemorrhage. The parts are represented in fig. 14. In an abscess of the neck, involving the thyroid artery, asphyxia has been suddenly induced by the escape of blood into the windpipe. Billroth met with an abscess at the base of the skull, in which, in consequence of disease of the internal carotid artery, death finally resulted from profuse hemorrhage of the right ear, nose, and mouth despite the ligation of both common carotids.

Artificial evacuation may be effected with the knife or with caustic. The latter, at one time so much in vogue, is now seldom employed, and it would be difficult to conceive what possible advantage it could possess over the former, which is incomparably more expeditious, less painful, and more certain. A surgeon should not so far humor a patient as to use caustic when his judgment plainly condemns it, simply because he is foolishly timid, especially now that all apprehension and suffering may be so readily prevented by the administration of anæsthetics; nor should he, on the other hand, resort to caustic with the view of promoting suppurative action, since there are always at our command articles far more desirable and efficacious. If, however, such a remedy should be called for, the best one is Vienna paste, applied as in making an ordinary issue, the eschar being afterwards penetrated, if need be, by the bistoury, now no longer dreaded by the patient.

Various instruments are employed for opening abscesses. The awkward, clumsy thumb lancet, which formerly figured so conspicuously in every pocket-case, is now seldom used, having been advantageously superseded by the scalpel and bistoury. The scalpel is, however, rarely employed, except in very large abscesses, when it is necessary to make a very free division of the overlying structures. By far the neatest contrivance for the purpose is the little bistoury, represented in fig. 15, which I have used almost exclusively for
Fig. 15.
Abscess Bistoury.

many years. It consists of two very narrow, sharp-pointed blades, one straight, and the other slightly curved, short, yet long enough to reach to the desired depth in almost any conceivable case. Selecting the most prominent, and, if possible, also the most dependent, portion of the abscess, the instrument is plunged perpendicularly through the skin, into the very midst of the matter, its arrival there being indicated by a want of resistance and probably also by an escape of a few drops of fluid, especially if this be thin. The puncture thus made is then converted into an incision, by depressing the handle of the bistoury, and cutting from within outwards, the length of the opening varying, on an average, from a third of an inch to an inch, according to the volume of the abscess. In general, it is better that the opening should be too large than too small, as the object always is to afford free vent to the pent up fluid. Care, of course, is taken, in introducing the bistoury, not to interfere with any important vessels and nerves, or to perforate any important cavity.

In large abscesses, attended with great destruction of the connective tissue, and extensive separation of the muscles, the course of the arteries is sometimes completely changed by the pressure of the accumulating fluid; and hence the surgeon, if not fully upon his guard, may, in making this puncture or incision, cause very serious, if not fatal hemorrhage. The best way to avoid such an accident is to ascertain carefully, beforehand, the situation of the vessel, as may usually be done by its pulsation.

When the abscess is very deep seated, as, for instance, when it occupies the muscles of the thigh, the walls of the abdomen, the groin or axilla, the safest plan is to divide the skin and fascia freely with the knife and grooved director, employed in the same cautious manner as in the removal of a deep-seated tumor.

Penetration having been effected, the matter usually escapes of its own accord, simply by the pressure of the atmosphere; but the evacuation may be aided, if necessary, by the hand or finger, used, however, with the greatest gentleness, otherwise it may occasion not only severe pain, but an aggravation of the inflammatory action. Too much caution, indeed, cannot be observed in this particular. Nothing can be more reprehensible than the rude manipulations that are so often practised after this operation, even by surgeons otherwise well educated. To prevent the incision from healing by the first intention, and the necessity of the repeated use of a knife, a small, well oiled tent, made of old linen, is interposed between the edges, one extremity being carried a short distance into the now empty sac, and the other left slightly pendant externally, substitution being effected once in the twenty-four hours. Or, instead of a tent, a drainage tube may be used to carry off the matter as fast as it is formed; the caliber of the tube should be of good size, and the side openings should be large, otherwise they will soon become clogged, and thus become a source of mischief. The best application for the surface of the abscess is an emollient cataplasm or a cloth wrung out of tepid lead water; but this should not be made until bleeding has ceased, otherwise troublesome hemorrhage might ensue. As soon as the parts have become perfectly comfortable, the warm dressing is discontinued, on account of its relaxing tendency, a piece of lint, spread with simple cerate, or wet with olive oil, being used in its stead.

When the matter is seated in a bone, evacuation must be sought with the trephine; but the operation is not always successful, owing to the difficulty of the diagnosis.

When the abscess is of large size, or when it has occasioned extensive separation of the muscles, its sides should be approximated, after evacuation, by means of a thick and well-adjusted compress, secured by adhesive strips, or, in the event of the matter being seated in an extremity, by the common roller, extending upwards from the distal part of the limb, care being taken not to interfere with the artificial opening. In this way a cavity that might otherwise not close under several weeks, will often be effectually obliterated in a few days.

Large abscesses are often immensely benefited, especially if slow in healing, by being thoroughly washed out several times daily with weak solutions of carbolic acid, chloride

of zinc, or chlorinated sodium.   These fluids, judiciously used, allay fetor, arouse healthy action, promote repair, and lessen the danger of purulent infection.

An abscess is sometimes prevented from healing by the unfavorable position of its opening, whether natural or artificial, the matter accumulating in a kind of pouch, situated between the orifice and the bottom of the swelling.   Such a condition calls for what is termed a *counter-opening*, which is easily established by making an incision at the most dependent part of the sac, upon the end of a grooved director, introduced through the previous and now useless aperture.   Counter-puncture is often necessary in abscess of the neck and parotid region, from the gravitating tendency of the matter in these situations. Sometimes, again, an opening of this kind is called for on account of a change in the position of the part after the first operation, performed perhaps well enough at the time. Whatever may be the causes demanding it, patency is maintained with more care, if possible, than under ordinary circumstances.

Again, repair may be rendered tedious, if not impracticable, by the existence of a *sinus*, extending, perhaps, deeply among the surrounding parts, or, it may be, communicating with some natural cavity.   The most speedy and effectual remedy is incision with a bistoury upon a grooved director, inserted into the bottom of the track, the parts being thus laid into one, and permitted to heal by granulation, readhesion being prevented by the constant interposition of a piece of lint.   In the milder cases, steady and systematic compression sometimes succeeds in obliterating the abnormal channel; sometimes, again, gently stimulating injections are useful; and, finally, there is a class of cases in which the seton is worthy of trial.   In general, however, these means only serve to amuse the patient and annoy the surgeon, who is at last compelled to have recourse to a remedy which he should have employed in the first instance.

Hemorrhage from extension of ulcerative action into a neighboring artery or vein may be so profuse as to endanger if not destroy life, either speedily or more or less remotely. In most cases it will be found to be very troublesome from the difficulty that is experienced in ascertaining its source.   The proper remedy is the ligature, the vessel being seized and drawn out with the forceps or tenaculum, or compressed with a needle confined with a stout thread, after the manner of a twisted suture.   Gentle compression sometimes answers the purpose, especially if the bleeding be venous, or if it proceed from a number of small points.   If an artery of considerable size has been opened, and cannot be easily reached, the incision should be enlarged to effect the necessary exposure.

When the bleeding is capillary or when the blood escapes from numerous points, as it sometimes does when the vessels have lost their support, from their inability to contract and retract, in consequence of the destruction of the connective tissue and the effusion of plasma, the best plan generally is to lay open the abscess freely, and to cover the raw surface with lint, wet with a solution of subsulphate of iron, and confined with a compress and bandage.   In a case recently under my care, in which a chronic phlegmonous abscess of the nates had been the seat of repeated copious hemorrhages, I exposed the entire cavity, turned out the clotted blood, and scraped away all the unhealthy granulations, thus placing the parts in a proper condition for rapid repair.   No bleeding occurred afterwards.   The coagula which had been confined in the abscess had evidently contributed to keep up the hemorrhage.

When an artery or vein of considerable size has been accidentally opened, the treatment must be conducted upon the same general principles as when the hemorrhage is produced by ulcerative action.   If direct means fail, the main trunk of the vessel, especially if it be an artery, must be exposed and ligatured.   In such a case no delay should be permitted in applying the proper remedy.

The *healing* of an abscess, whatever may be the manner of its evacuation, is effected by the contraction and approximation of its walls, which generally begin the moment the matter has escaped, and steadily progress until the sac is completely obliterated.   The raw state of the opposed surfaces strongly predisposes them to unite with each other, an occurrence which is always favored by an effusion of plasma.   If the cavity of the abscess were obliterated, as was formerly supposed, by granulations, the part would remain hard and prominent for a long time; but this is not the case.   On the contrary, it soon shrinks, becomes soft, and drops down to a level with the surrounding surface.   The opening alone unites in this way; but even this is not always so, for examples constantly occur of closure by the first intention.

Although the outer wall of the abscess generally soon recovers its pristine softness and pliancy, occasionally the reverse is true, the parts remaining hard, tender, enlarged, and seemingly reluctant to throw off their inflammatory burden.   To expedite resolution, the

affected surface may be covered with an ammoniac and mercurial plaster, commonly the very best remedy that can be used for the purpose ; or it may be rubbed several times a day with some sorbefacient liniment, unguent, or embrocation, aided, perhaps, by the bandage and a few alterative doses of mercury. A bran poultice, prepared with salt water, is often a most efficient application.

Constitutional treatment must not be neglected. Indeed, there are few cases in which this is not absolutely necessary. This is especially true in all severe cases of phlegmonous abscesses, in which the copious discharge of pus, the high fever, and profuse sweats so generally present, always establish a serious drain upon the system. The remedies mainly to be relied upon are quinine and iron, particularly when there is marked anemia, quinine and the mineral acids, milk punch, beef essence, and, above all, opium and fresh air. When convalescence is unusually slow, a residence at the seaside often proves beneficial ; and when digestion and assimilation are seriously at fault, cod-liver oil will be worthy of trial. For the relief of night-sweats the best remedies are aromatic sulphuric acid, atropia, or oxide of zinc, either alone or in union with opium.

2. DIFFUSED ABSCESS OR PURULENT INFILTRATION.

The above is one variety of phlegmonous abscess ; the circumscribed, in which, united with rapidity and severity of action, the matter is bounded by a distinct wall of fibrin, serving the purpose of a cyst, although in reality there is no such formation. In the present variety, already incidentally adverted to, there is no connective exudation, and the consequence is that the pus is widely diffused among the surrounding structures, dissecting and separating them from each other in the most frightful manner. Such collections, which are generally attended with intense suffering, are often described under the appropriate and expressive appellation of purulent infiltrations, the result always of cellulitis.

The diffused form of abscess is met with under a great variety of circumstances, both as it respects the nature of the exciting cause and the condition of the general system. It is most common in persons whose constitution has been dilapidated by intemperance in eating and drinking, by want and exposure, and by organic affections of the heart, lungs, liver, bowels, and kidneys, leading to anemia, obstructed circulation, and exhaustion of the vital powers. When such persons meet with a serious accident, or suffer from a prolonged attack of fever, suppuration is extremely prone to take on this kind of action, often sadly complicating the original disease. Diffused abscesses are also sufficiently common after severe injuries, as compound fractures and dislocations, lacerated, railway, gunshot, and dissection wounds, and capital operations, especially amputations of the larger limbs and resections of the bones and joints. Persons of a scrofulous constitution are, on the whole, more liable to suffer from diffused suppuration than any other class of individuals, their vital powers being too feeble to furnish a sufficiency of fibrin to limit the purulent matter.

Diffused abscesses may occur independently of any other appreciable disease, or they may arise in conjunction with erysipelas, pyemia, or phlebitis, which they resemble very much both in their mode of origin and in the character of their symptoms. Their presence, in fact, is always denotive of a bad, depraved, or degraded state of the system ; in some cases the fault apparently lies in the blood, either in a defect of some of its more important constituents, or in the ingress of some morbid poison ; in others, again, it seems to be due to imperfect action of the skin and kidneys, excess of food and drink, the respiration of impure air, overaction of the brain, or exhaustion of the nervous system.

The symptoms of this variety of abscess are ordinarily bold and well defined. In general, the disease is ushered in by considerable shivering, if not by a severe rigor, followed by heat and perspiration ; the pulse soon becomes small, quick, frequent, and irritable ; the extremities are cold, the urine is scanty and high-colored, the appetite is destroyed, the tongue is covered with a brownish fur, the strength rapidly declines, and the patient soon sinks into a state of delirium. Great irritability of the system exists ; the pain is often excessive, sleep is interrupted, and the mind is peevish and fretful. Frequently the symptoms are of a typhoid character from the beginning ; if not, they are sure soon to become so ; and yet not merely typhoid, but typhoid and irritative, the two classes being generally well balanced throughout.

The local symptoms are those of ordinary inflammation, only that they are more severe, especially when the matter is deep seated. The discoloration is of an erysipelatous nature, the parts are swollen and pit on pressure, the pain is smarting and pulsatile, and

the skin feels hot, stiff, and numb.   If the matter lies immediately beneath the surface, or among the more superficial muscles, a boggy sensation will be imparted to the hand of the examiner, and a little pressure will be sufficient to push the fluid about from one place to another, sometimes to a distance of many inches.   When, on the contrary, the pus lies far below the surface, bound down by muscles and aponeuroses, its early detection will generally be very difficult; under such circumstances, the best guide to its situation will be the history of the case, the deep-seated pain, the presence of œdema of the skin and connective tissue, and the character of the constitutional phenomena.   If any wounds or sores exist, they speedily dry up, and assume an unhealthy appearance.

Although any part of the body may become the seat of diffused abscesses, their most common sites are the limbs, in which the matter often burrows to a great extent, both beneath the integuments and among the muscles; in some of the worst forms that I have ever seen, it lay in immediate contact with the bones, separating them from the soft structures, and even from the periosteum.   In one case under my observation, the fluid had spread along the posterior surface of the lower extremity, in close contact with the femur and the bones of the leg, from the hip as far down nearly as the heel.   The matter is generally thin, sanious, irritating, acrid, and excessively offensive, often tainting the atmosphere of the apartment for many feet around, and fastening itself upon the hands and clothes so as to be perceptible for hours afterwards, notwithstanding, perhaps, the liberal use of deodorizers.   In fact, the stench is usually most disgusting.   In some cases the fluid approaches more nearly to the properties of ordinary pus, but this is uncommon.   Occasionally extensive sloughs form, especially in the connective tissues, so that the disease may be said to partake of the character both of suppuration and of gangrene.

The prognosis of this form of abscess is generally very unfavorable, few constitutions being able to withstand its depressing effects.   The very fact that such a disease is in operation shows, as already stated, that the system is in a depraved condition; and when it is recollected that some of this foul matter must necessarily find its way into the circulation, contaminating everything with which it comes in contact, it is not difficult to anticipate what the result will be likely to be, even when the purulent collection is not very extensive, especially in persons already exhausted by shock, loss of blood, or lesion of some important organ.

The *treatment* of diffused abscess is sufficiently obvious.   The leading indications are to evacuate the matter, and to support the system.   The first is fulfilled by early and free incisions, practised at the most favorable site for ready drainage, with the precaution of avoiding hemorrhage, the smallest quantity of which is sometimes sufficient, in such an event, when life is, as it were, quivering in the balance, to bring on fatal exhaustion.   Counter-openings are often necessary.   After the abscess has been thoroughly evacuated and cleansed, its sides are gently approximated with the bandage, a means of support of the greatest value, not only in preventing the extension of the matter, but in promoting the healing of the parts.   So long as the fluid is offensive, the abnormal cavity should be well syringed several times a day with tepid water, charged with a suitable quantity of chlorinated sodium and permanganate of potassium, or creasote, chloride of zinc, acid nitrate of mercury, or carbolic acid, to correct fetor, and to impart tone to the disabled structures.   Any sloughs that may form should be speedily removed, the knife being used, if necessary, to effect their separation.   The parts are placed in a proper position for facilitating drainage, and are enveloped in warm-water dressing, or an emollient medicated poultice, with acetate of lead and opium.   Compression is steadily employed until the sac is obliterated.

Among the more valuable internal remedies are anodynes, quinine, iron, and brandy, with animal broths and soups, and a pure atmosphere, which is of paramount importance to recovery.   The windows and doors of the apartment should be frequently thrown open, the dressings changed, and disinfecting agents used.   Anodynes are indispensable to allay pain and induce sleep, and should be administered in full doses, in the form of morphia, opium, or black drop.   The best tonics are quinine and brandy, given in the same manner as in typhoid fever; the tincture of chloride of iron, in doses of fifteen to twenty drops, every three or four hours, will also be of service; and, in many cases, ammonia, in camphor mixture, will meet the exigencies of the case better than almost any other remedy, especially if there be hiccough with twitching of the tendons.

3. SCROFULOUS ABSCESS.

The scrofulous abscess is known by various names, some of which have reference to its progress, some to its symptoms, some to the nature of its contents, or to the state of the constitution preceding and accompanying its formation. Thus, it is often described as the chronic abscess, tardy development being one of its characteristic features; the word cold is frequently employed on account of the absence of inflammatory symptoms; but scrofulous is the appellation by which it is generally distinguished at the present day. As implying the same thing, the terms strumous and tubercular are much in vogue. There is a form of this abscess to which the name congestive has been applied, from its tendency to change its position, although it is impossible to discover any etymological fitness in it.

The scrofulous abscess is altogether a singular affection; singular in its origin and progress, its termination and its treatment. It is never met with, except in the strumous constitution. The phlegmonous abscess is common to all persons, of every age, grade, and condition in life; the scrofulous, on the contrary, can only occur in persons who have a predisposition to scrofulous affections, whom nature has stamped, so to speak, with a peculiar diathesis, or state of the system, rendering them prone to phthisis, coxalgia, caries of the spine, and kindred maladies. Its sphere of action is, therefore, comparatively limited, a hundred cases of phlegmonous abscess occurring to one of a scrofulous character.

The progress of the scrofulous abscess is always slow, weeks and months usually elapsing before it acquires any considerable bulk: hence the term chronic, by which it is so frequently designated. A phlegmonous abscess, on the contrary, is always rapid in its progress, generally attaining its full development in a very short time. Another peculiar feature of the strumous abscess is the absence of the ordinary inflammatory symptoms. The skin, instead of being hot and red, is cold and blanched, the part feeling and looking as if there were great deficiency in its circulation. Hence this variety of abscess used to be termed cold, especially by the German surgeons, who were the first to describe it. Pain, too, is absent, or, if it exist, it is so trivial as hardly to attract attention. Functional disorder also is very slight, especially in the earlier stages of the disease. Looking at the constitution, the same uncommon train of phenomena is observed. The general health may be somewhat impaired; the strength may slowly and almost imperceptibly decline, and the countenance may have a pale, sallow appearance; but there are none of the open and well-marked inflammatory symptoms which attend the march of a phlegmonous abscess, and which, especially when the disease is located in an important internal organ, suggest the idea of great and immediate danger. Thus, as far as appearances are concerned, the affection is one seemingly of little moment; its discovery is often purely accidental, and, for a while, both patient and surgeon may be wholly unconscious of its true character. It is, indeed, as completely different from an ordinary abscess as it is possible for one disease to be from another. Scarlatina and measles are not more unlike each other.

The strumous abscess is very frequent in the lymphatic glands, subcutaneous connective tissue, and in the dorso-lumbar region. The testicle, breast, and liver are also sometimes its seat. It is, however, more common in the lungs than anywhere else, for there it is the immediate product of the softening of tubercular matter, eventuating generally in the formation of what are termed vomicæ or pulmonary caverns. In the external parts of the body it is usually situated in the neck, on the chest, in the axilla, on the loins, in the groin, or upon the superior portion of the thigh. Large strumous accumulations sometimes occur in the movable joints.

As to the size and number of these abscesses, considerable diversity obtains. In certain situations, as in the lungs, they are always small, but at the same time often very numerous; while in others, as in the cervical glands, on the chest, in the groin, and on the back, they are usually single, and from the volume of an orange to that of a fœtal head.

The strumous abscess is nearly always furnished with a distinct cyst, called the *pyogenic* membrane, which, while it serves to individualize it, separates it effectually from the surrounding parts. At what period of the suppurative process the membrane appears is not determined, but that it is developed at an early stage is unquestionable. It has been supposed that its formation, at times, precedes the formation of the pus. The subject, however, does not admit of easy demonstration; for it is seldom that an opportunity is afforded of inspecting such an abscess until after it has attained considerable bulk, and the membrane has acquired some degree of development. The most plausible conjecture,

perhaps, is, that the membrane is formed as a matter of necessity, nature intending it as a means of limiting the diffusion of the pus, as would otherwise inevitably happen in consequence of its tardy but steady deposition. To accomplish this object, she sets up around the purulent depot, at an early period of the morbid action, a species of adhesive inflammation, by which, in the first place, the cells of the neighboring tissues are effectually occluded, the process being precisely similar to that which occurs in an ordinary phlegmonous abscess. Thus, the fluid is temporarily circumscribed, but, as may readily be perceived, the barrier thus opposed would soon yield before the accumulating burden, and thus thwart nature's intentions, if it were not that a wall of plastic matter is next constructed, which no amount of pus, however great, can, for a time, break down or destroy. The thickness of this wall varies from the eighth of a line to the eighth of an inch ; its density steadily increases with its age, and hence it is often found to be of a fibrous consistence, with here and there a semi-cartilaginous patch. Its outer surface is rough and intimately united with the surrounding structures ; the inner, on the contrary, is either perfectly smooth, or studded with minute granulations, not unlike the villi of the small intestine, only not so regular and numerous. Its vascularity, which is always considerable, is easily distinguishable by the naked eye, as well as by minute injection. It also, no doubt, contains nerves and absorbents, although they are not demonstrable.

No one can reflect upon the structure of this membrane without being impressed with the conviction that it is invested with important functions. In the first place, as already stated, it protects the tissues in the immediate neighborhood of the abscess from the diffusion of its contents ; a circumstance which could not fail to be productive of great injury, inasmuch as the matter, burrowing about in different directions, might occasion extensive separation of the muscles, which it would afterwards be extremely difficult to remedy. Secondly, the membrane is an important secreting structure, since it furnishes the matter which it incloses, either directly, or indirectly through the agency of lymph, speedily transformed into pus. Thirdly, it is also an absorbing structure, as is proved by the fact that the matter which it contains occasionally disappears, either spontaneously, or under the influence of treatment. Finally, the membrane possesses important sympathies with the rest of the system. Left to itself, it causes no general disturbance, but the moment it is opened so as to admit the entrance of air, it resents the aggression, and is sure to occasion severe constitutional derangement.

The pus of a strumous abscess is generally of a whitish or yellowish cast, slightly inclining to greenish, of a tolerably thick consistence, free from odor, and intermixed with caseous particles, looking and feeling very much like pieces of soft-boiled rice. Instances occur, especially in scrofulous disease of the lymphatic glands of the neck, where it is very thin, pale, and full of curdy substance, consisting apparently of imperfectly broken-down tubercular matter. When long retained, or situated near the anus and rectum, scrofulous pus is sometimes excessively fetid, either from actual decomposition or from the presence of sulphuretted hydrogen. Permitted to stand for some time, it separates into two parts, one of which is thin, whey-like, or sero-oleaginous in its appearance, the other thick and curdy, the former being always upon the top of the latter. Like the pus of a phlegmonous abscess, it occasionally contains the debris of the organs in which it is formed, and also some of their peculiar secretion. Thus, a strumous abscess of the liver may contain bile ; of the breast, milk ; of the spine, osseous particles. The microscopic characters of scrofulous pus are well illustrated in fig. 19, from Jones & Sieveking.

In regard to quantity, there is much variety in the pus of this form of abscess. In psoas abscess, one of the best examples of the disease, the accumulation is sometimes enormous, reaching several quarts, or, perhaps, even a gallon. In scrofulous abscess in the glands of the neck, there is also occasionally a good deal of pus, although, in general, it is small. Large collections of strumous matter are sometimes seen in chronic abscess beneath the skin, especially in the lower extremity. A young woman, a patient at the College Clinic, had an abscess of this kind on the left thigh, containing nearly a gallon of pus.

The contents of a chronic abscess are sometimes remarkably thin and pale, or almost watery, being composed essentially of the serum of the blood, with few, if any, well-developed pus globules. Flakes of fibrin and broken-down connective tissue are occasional ingredients of such fluids, which sometimes exist in enormous quantities, especially in young, scrofulous subjects,

Fig. 16.
Pus from a Scrofulous Abscess.

of an anemic appearance and dilapidated constitution. The pyogenic membrane, also, is generally uncommonly thin and imperfectly organized. Abscesses of this kind, formerly known as lymph abscesses, are most common about the hips and nates, and in the upper part of the thigh.

The diagnosis of the strumous abscess may be gathered from the remarks already made respecting that of phlegmonous abscess. The principal affections with which it is at all likely to be confounded are aneurism, and various kinds of tumors, as the cystic and sarcomatous. In the groin and upper part of the thigh such an abscess might be mistaken for hernia. From these affections, however, it may usually be easily distinguished by the history of the case, the fluctuating character of the swelling, and, if necessary the use of the exploring needle, the latter of which seldom, if ever, fails to furnish the requisite light.

When a cure takes place in a strumous abscess, whether spontaneously or by art, the cyst gradually shrinks, and is ultimately completely obliterated, the wall itself finally disappearing. In exceptional cases, however, a portion of the structure remains, generally in an unsound condition, and, therefore, liable to fresh attacks of inflammation, years, perhaps, after the apparent obliteration of the sac. Such an event will be the more likely to occur when, as not unfrequently happens, some of the contents of the abscess are retained in the form of half-dried, shrivelled, and disintegrated matter, which may thus, at any time, become a source of irritation, provoking not only inflammation, but more or less profuse suppuration, the development of abscesses, and constitutional disturbance. These residual or recurring abscesses are most prone to form in connection with Pott's disease of the spine, and other portions of the skeleton, generally as a consequence of external injury, or protracted disease, seriously undermining the vital powers.

Treatment.—The treatment of this abscess differs essentially from that of the phlegmonous. In the latter, the system often bears energetic measures ; in the former, seldom, if ever; in the one, the surgeon does not hesitate to make an early and free incision into the swelling, with a view to the early evacuation of its contents ; in the other, he waits and hesitates, well knowing that such an operation is often the prelude to serious constitutional disturbance, if not death. The one is the work of a few days, or, at most, of a few weeks, taking the part and system, as it were, by surprise, and, therefore, requiring prompt interference ; the other is the work of time, affording the part and system an opportunity of accommodating themselves to its presence, and, therefore, often intolerant of interference. When the quantity of matter is small, removal is occasionally effected by absorption, the process being sometimes advantageously aided by internal and external remedies, especially the iodide of potassium and the bichloride of mercury, together with sorbefacient plasters, unguents, and embrocations. These means are more particularly available in chronic abscesses of the glands of the neck, groin, and axilla, and in those of the mamma and subcutaneous connective tissue. In psoas and lumbar abscesses, on the contrary, little or no benefit usually results from their employment, beyond the influence which they may exert in improving the general health, and in eradicating the strumous diathesis. When general debility exists, relief should be attempted with tonics, as quinine and iron, along with cod-liver oil, milk punch, and change of air.

When a scrofulous abscess is seated in an external part of the body, as the mamma, a lymphatic gland of the neck, or the subcutaneous connective tissue, the only rational treatment is the evacuation of its contents. In such cases, indeed, it is hardly possible to make too early or too free an incision ; for, not only is there, generally, no danger of causing constitutional disturbance, but the procedure is eminently calculated to save structure and promote recovery. The matter being thus disposed of, the cavity usually at once contracts, and, the tendency to secretion gradually diminishing, the part finally heals by granulation or adhesion. Besides, such a procedure always enables the surgeon to watch the morbid action, and to apply his remedies directly to the affected surface.

The best local applications, after the abscess has been punctured, are emollient poultices, rendered slightly stimulating by the addition of a little common salt ; or tincture of iodine, spirituous lotions, or some sorbefacient plaster, as the ammoniac and mercurial, soap, compound galbanum, or iodine plaster, care being taken to leave an appropriate opening for the discharge of matter. I can speak with great confidence of the beneficial effects of these agents, especially the first, from my experience of them in the treatment of strumous abscess of the neck, mamma, and subcutaneous connective tissue. When the cavity of the abscess is slow in healing, on account of the torpor of its vessels, or the existence of a strong pyogenic membrane, nitrate of silver, carbolic acid, acid nitrate of mercury, or chloride of zinc, may be employed, in the form of weak injections, as local stimulants,

until there is a disposition to the formation of healthy granulations. Sometimes, as in the case of a subcutaneous abscess, a seton may advantageously be introduced, retention being maintained until the sac is obliterated by inflammation. Or, instead of this, a counter-opening may be made, and a tent inserted. Or, if the sac is small, it may be dissected out. As a rule, when the abscess is small, the best plan is to lay it freely open, and to scrape away all unhealthy and disintegrated matter, a step which wonderfully promotes the cure.

When the abscess is connected with disease of the bones, as it generally, if not always, is when it takes the name of psoas or lumbar abscess, the treatment formerly in vogue was that originally suggested by Abernethy, which consists in making a valve-like open-ing into the most prominent or most dependent part of the swelling, and drawing off only a portion, as one-half or two-thirds of its contents at a time, the operation being repeated every fourth or fifth day according to its effect. Educated in a school in which this practice was strongly inculcated, and warmly prepossessed in its favor, I followed it until the accumulated experience of many years satisfied me of its utter uselessness, and I therefore abandoned it. The treatment which I now pursue, is simply to evacuate the matter at the earliest possible period by a moderately free incision, and to wash out the sac most thoroughly with warm water, charged with chlorinated sodium, carbolic acid, or permanganate of potassium, and introduced with a gum elastic syringe. A full anodyne is administered either a short time before or immediately after the operation, and is repeated twice daily for at least one week. The object in giving the anodyne in this way is to prevent undue reaction after the evacuation of the matter, which will otherwise be sure to occur, and to lead to hectic irritation, and great prostration of the vital powers. I was induced to adopt this practice many years ago from observing its beneficial effects in cases of this kind, and can, therefore, warmly recommend it. The medicated injections should be repeated at least twice in the twenty-four hours, the fluid being always thrown into the sac in such a manner as to distend its walls, and thereby promote the thorough cleans-ing of their free surface; in other words, every effort should be made to prevent the accumulation and retention of decomposed and offensive secretions. A drainage tube, of some kind or other, should be retained in the abscess. The best local application, for some time at least, is an emollient poultice or warm-water dressing, medicated with lauda-num and acetate of lead. The patient is kept at rest and supported by tonics, such as quinine and iron, with nutritious food and drink. As the strength improves, exercise is employed in the open air, and advantage taken of a change of air, with, if possible, a residence at the seaside, always so beneficial in exhausted states of the system.

The antiseptic treatment of a scrofulous abscess, through which it is asserted that putre-factive changes in the pyogenic membrane may be prevented, is conducted in the following manner: The skin having been thoroughly washed with a one-to-twenty solution of carbolic acid, a one-to-thirty carbolic spray is directed upon and around it by a steam atomizer, when the abscess is opened freely with a bistoury which has been dipped in a solution of the former strength. When the pus has discharged itself, the lightest pressure alone being permissible to favor its escape, a carbolized drainage tube is inserted, the incision is covered with a bit of oiled-silk protective, and the dressing is completed by retaining upon the part antiseptic gauze, between the seventh and eighth layers of which a piece of mackintosh has been inserted. The first six layers of the gauze, as well as the protective, should be moistened with a one-to-forty carbolic solution before they are applied. The dressing need not be changed for several days unless the occurrence of fever or of profuse discharge demands it. Oil of eucalyptus may be substituted for the carbolic acid, as it is said to be equally as effective as that agent. This method of treatment is still employed by many surgeons, but I regard it as utterly useless.

It has been proposed to open these abscesses while the patient's body is immersed in water, on the ground that there would thus be less likelihood of the introduction of air; but it may well be asked whether the ingress of the former fluid would not be quite as injurious as that of the latter? The truth is, it is hardly possible to perform the opera-tion without some risk of this kind, although, if proper care be taken, the quantity will not be so large as to produce any serious mischief.

As to iodine injections, recommended for the radical cure of this form of abscess, the experience of the profession offers nothing in their favor. The practice, considered in a purely theoretical point of view, is sufficiently plausible, inasmuch as its object is to change the character of the secerning surface of the pyogenic membrane, by inviting an effusion of plastic matter, with the hope of effecting the obliteration of its cavity. It was evidently suggested by the beneficial effects which are known to follow the use of iodine

injections in hydrocele and kindred affections, but to insist upon a similarity of structure of the sac of a chronic abscess and of the vaginal tunic of the testicle certainly evinces a very imperfect knowledge of morbid anatomy. It is not surprising, therefore, that the practice should have failed, and that its employment should have been attended, in most cases, with considerable risk, from its tendency to create undue irritation both in the part and system.

4. HECTIC FEVER.

Hectic fever, although not necessarily dependent upon suppuration, is yet so closely connected with it, as a common result of that process, that it may very properly be described under the same head. Its existence is nearly always indicative of serious organic lesion, of which it, therefore, constitutes merely the general expression. The word hectic, literally signifying a bad habit of body, was originally employed to designate the peculiar train of phenomena attendant upon pulmonary phthisis, of which it forms so remarkable an attribute as to have attracted the attention of practitioners in all ages. It is, however, no longer restricted to such narrow limits; for the group of symptoms which it serves to characterize follows upon a great number of diseases, accidents, and operations, and, therefore, claims the special consideration alike of the surgeon and the physician.

Hectic fever never occurs as an idiopathic affection; on the contrary, it is always symptomatic of some particular disease, generally of the presence of profuse discharge, as of pus or blood, or the existence of an abscess in some important structure, as the brain, lung, or liver. One of the most remarkable circumstances connected with its history is, that it rarely, if ever, appears until the malady which it serves to represent has made considerable progress, or induced serious structural changes, along with grave inroads upon the constitution. Thus, in phthisis, it is seldom witnessed until softening of the tubercular matter is about to take place, sometimes, indeed, not until large cavities have formed; on the other hand, there are cases, as in psoas abscess, where pus frequently exists in large quantity, perhaps for several months, and yet none of the ordinary signs of hectic fever arise. Serious as the local disease apparently is, the general system does not seem to be disposed to take any particular notice of it; the pulse, sleep, appetite, bowels, and secretions all go on nearly in their accustomed manner; and, if there be any loss of flesh and strength, the alteration is so gradual and imperceptible as almost to elude the attention even of the patient himself. But sudden and often most alarming changes occur in the constitution if, in consequence of a large opening, air is freely admitted into the cavity of such an abscess, causing decomposition of its contents. The shock is violent, and resentment of the injury is close at hand; soon a severe rigor comes on, lasting, it may be, several hours, when it is succeeded by violent fever, as this, in its turn, may be followed by copious sweat. Such is not unfrequently the commencement of an attack of hectic fever, a bad habit of body, which often ceases only with the patient's life. Thus, it will be perceived that hectic fever, like every other form of fever, at least so far as we can comprehend its nature and type, is not a disease, but a symptom of disease, an expression of general suffering, dependent upon some special local lesion, not always, perhaps, appreciable by our senses, yet, nevertheless, in active operation, and effectually accomplishing its work.

In traumatic affections, hectic fever often sets in at an early period after the accident; perhaps there may have been grave shock and profuse hemorrhage, and the two are soon followed by copious suppuration, which thus still further undermines and exhausts the vital powers; or it may be that more or less of the pus has been carried into the circulation, and that the whole system has become poisoned by the unfortunate admixture, every blood globule and every fibre and atom of solid matter feeling the baneful influence. The brief struggle which ensues may be characterized by the inflammatory type; but this is evanescent, hectic soon taking its place, and thence on steadily maintaining the ascendency, no intercurrent circumstances ever changing its true character, although they may temporarily disguise it, or for a time keep it in abeyance.

Hectic, then, is a continued, remittent fever, persisting generally so long as the cause which induced it lasts; subject to distinct paroxysms of exacerbation and remission, but at no period, perhaps, completely absent, although apparently it may be. Its outbreak is often sudden and violent, sweeping over the system with the fury of a hurricane; at other times, and more generally, it creeps on gradually and stealthily; in the former case it is marked by severe rigors, in the latter merely by a sense of chilliness, or slight hor-

ripilations.   Whatever may be its mode of attack, its actual invasion is always preceded by more or less indisposition, amounting ordinarily to a mere state of malaise, or a feeling of lassitude and discomfort, which the patient struggles in vain to throw off.   His appetite and sleep are impaired ; his tongue is inclined to be dry, perhaps somewhat coated ; more or less thirst exists ; and there is often considerable fever, either of the inflammatory, irritative, or typhoid type.   In short, hectic, like every other fever, passes through a stage of incubation, brief in one case, protracted in another.   The crisis being attained, the chill appears, and thus the disease is fairly inaugurated; taking its position in the system, which, as already stated, it never abandons until the removal of the exciting cause, and often not then.

The febrile exacerbation is usually vesperal, coming on late in the afternoon, or early in the evening ; lasting, on an average, from six to nine hours, and then gradually going off, to reappear, in a similar manner, about the same time the next day, thus giving the disease a distinct periodical character, not unlike that of an ordinary intermittent.   Not unfrequently there are two paroxysms in the twenty-four hours ; one in the evening, and the other, perhaps, late at night, or during the course of the morning; the latter being generally much the milder of the two.   The chill ushering in the fever is often very long and severe, the patient occasionally shivering for several hours, his teeth chattering violently, and the whole body feeling as if it were wrapped in ice ; at other times, as already intimated, the sensation of cold is very slight, and, perhaps, perceived chiefly along the spine, shoulders, and lower extremities, its duration being variable, now short, now quite protracted.   The chill passing off, reaction succeeds, usually violent in proportion to the previous depression, the temperature, however, rarely exceeding 103.5° Fahr., and gradually, sometimes suddenly, merging into a profuse sweat, the harbinger of returning ease and comfort.   All the secretions are again unlocked ; the mouth regains its moisture ; the urine is poured out in increased quantity ; the thirst rapidly subsides ; the pulse becomes soft and comparatively calm ; and ere long the poor patient, tortured and racked with suffering, falls into a tranquil and refreshing sleep.

In the interval of the paroxysms, the patient, although comparatively comfortable, is by no means entirely free from excitement.   The pulse, in particular, is always preternaturally frequent, often even quick and small ; seldom entirely normal in any case or at any time ; easily disturbed by exercise and mental emotion.   The countenance exhibits well-marked evidence of the inward trouble ; in the morning it is pale, shrunk, and careworn ; in the afternoon, on the contrary, it has generally a somewhat full appearance, and a circumscribed blush, too plainly denotive of the vital decay, rests upon the cheeks in striking and often mournful contrast with the surrounding pallor.   The eyes have a peculiarly lustrous expression, and gradually retreat more and more within their sockets.   Emaciation begins early, and is steadily progressive, proceeding from bad to worse, until the body is literally wasted away to a skeleton.   Amidst all these evidences of decay, it is remarkable how well the appetite frequently sustains itself ; the patient often eats voraciously in the intervals of his paroxysms, and digestion goes on with little or no interruption, assimilation alone being at fault.   The tongue is variously affected ; in general, however, it is clean, or nearly clean, but, perhaps, a little too red at the tip and edges.   At times it is very smooth and glossy ; and cases occur in which it appears to be glazed, as if it were coated with a thin layer of mucus.   A foul tongue is a rare phenomenon in this form of fever.   Hectic patients are usually easily impressed by atmospheric vicissitudes ; the slightest exposure produces chilliness, and hence they always require an unusual amount of clothing.   The feet and legs, in particular, are nearly incessantly cold ; the hands on the contrary are generally dry, hot, and burning.

As the disease occasioning the hectic progresses, the symptoms gradually manifest more and more of a downward tendency ; the appetite fails, the sleep is interrupted, the perspiration is more profuse and exhausting, aphthae appear upon the tongue and fauces, and the bowels are constantly harassed with diarrhœa, the discharges being thin, watery, and excessively fetid.   Thus, the case goes on, steadily but almost imperceptibly, from bad to worse, until the patient dies literally exhausted, by the want of nourishment, and, perhaps, also by the severity of his bodily pains.   During all this struggle, it is astonishing, to see how the mind, rising above the mortal decay around, maintains its supremacy, being not only clear and strong, but hopeful and often even sanguine to the last.

The progress of hectic fever is influenced by such a variety of circumstances as to defy anything like a definite statement.   In general, it promptly disappears with the removal of the existing cause, provided the inroads made by it have not been productive of any serious disorganization ; should this have happened, the case will probably have an un-

favorable issue, the hectic continuing in a modified form down to the fatal crisis. Operative interference often exercises a wonderful influence under such circumstances. I have repeatedly seen a severe and protracted hectic, consequent upon the destruction of a tuberculosed joint, completely vanish in less than twenty-four hours after amputation, and the system rapidly recover from the effects of the previous disturbance.

The indications in the treatment of hectic fever plainly are, first, to remove the exciting cause, and, secondly, to support the system until it has an opportunity of shaking off the effects of the morbid action.

The first of these objects is frequently best accomplished by the knife, as when, for example, the disease depends upon, and has been kept up by, a tuberculosed joint, or a suppurating compound fracture, the removal of which often promptly restores health and tone to the prostrate system. If the cause be inaccessible, the case must be treated upon general principles, in the hope that, by and by, as the strength improves, the patient will have sufficient recuperative power to dislodge the source of irritation, and so get rid of his malady.

The second indication is fulfilled by tonics, nutritious food, anodynes, the suppression of unnatural discharges, change of air, and attention to cleanliness.

The use of tonics is generally indispensable in almost every case of hectic, however induced, particularly in its more advanced stages, when there is a wretchedly impoverished condition both of the blood and solids. The articles most to be relied upon are quinine, aromatic tincture of bark, and the different preparations of iron, of which, according to my experience, the sulphate and the tincture of the chloride deserve the preference. Whatever substance be selected, its operation should be aided by a nutritious diet, consisting of the richer kinds of animal broths, beef-essence, beefsteak, milk-punch, tapioca, arrowroot, and milk, whine whey, ale, or porter. When the emaciation is steadily progressive, and dependent upon a tubercular diathesis, cod-liver oil will be of service, and should be given in as large doses as the stomach may be able to bear.

Anodynes are among the most valuable agents in the treatment of hectic, as they serve to allay the inordinate action of the heart, to relieve pain and irritation, and to procure sleep, which is generally so much impaired in cases of this kind. They should be given in full doses, not too often repeated, the best period for their exhibition being usually towards bedtime, so that their appropriate effects may be realized during the night in refreshing tranquility. Morphia is generally better borne than opium, but when there is much sweat or diarrhœa, it may often be advantageously replaced by the latter, as more likely to produce an astringent influence.

The exhausting effects of diarrhœa and perspiration, especially when they are of a colliquative character, must be promptly counteracted by suitable remedies, of which opium, as just stated, is one of the best. When the diarrhœa is dependent upon vitiated fecal matter, a mild laxative should be given, and blue mass, or calomel, in minute doses, if it has been caused by derangement of the biliary secretion. Sometimes it is most readily checked by astringents, as rhatany, prepared chalk, or tannic acid, in union with an anodyne.

Night sweats, often a source of so much prostration, are best controlled by the free use of aromatic sulphuric acid, tannate of iron, oxide of zinc, or atropia, with frequent ablutions of the surface with tepid alum water. Atropia is especially valuable in controlling night sweats. It may be given by the mouth, in the dose of the fiftieth to the sixtieth part of a grain, or, what is preferable, in the form of a hypodermic injection, the average being the one-hundredth part of a grain. The injection need rarely be repeated oftener than once in twenty-four hours. Sometimes the sweats may be effectually prevented by a full opiate administered a short time before the expected rigors.

When the local disease, inducing the hectic, admits of it, exercise should be taken in the open air, which frequently conduces more to the restoration of the patient's appetite and strength, and the relief of the colliquative diarrhœa and sweats, than all other means combined. Children may be carried about in their nurses' arms, or in the hand car, while adults may ride about in a carriage, or walk, as may be most agreeable and convenient. Occasionally a residence at the seaside will be found to be eminently beneficial.

Finally, cleanliness is of the greatest possible importance; the body must be frequently washed and rubbed; the excretions carefully and promptly removed; and the apartment thoroughly ventilated at least twice a day, the windows being lowered in the mean time to admit of a constant supply of fresh air.

SECT. V.—SEPTICEMIA AND PYEMIA.

By septicemia is meant a febrile affection which is produced by the absorption of putrid material into the blood, and which is not accompanied by the development of metastatic abscesses. The term pyemia, on the other hand, is restricted to the fever which is caused by the entrance of septic material into the circulation, where it multiplies and gives rise to embolic abscesses. Both affections are frequently associated with each other, and pyemia is merely septicemia with the addition of certain inflammatory lesions.

Before entering into the separate consideration of these septic fevers, a brief sketch of the nature of the septic poison, which is the same in both affections, and of its mode of absorption affords an interesting field of inquiry. Gaspard, of St. Etienne, in France, as early as 1808, performed an elaborate series of experiments with putrefying fluids, with a view of ascertaining their effects upon the system when introduced under the skin or into the veins of animals. He found that, when the quantity was considerable, it invariably induced violent constitutional symptoms, attended with great gastric distress, and copious fetid and bloody alvine evacuations, rapidly followed by exhaustion and death. These researches were published in 1822, in Magendie's Journal of Physiology, but attracted little or no attention on the part of scientific men. During the past twenty years, however, the experiments of Weber, Billroth, Burdon-Sanderson, Koch, Hueter, Savory, Davaine, and others, have fully verified the results established by Gaspard three-quarters of a century ago, and have supplied us with a few additional facts, chiefly in reference to the existence of certain microscopic organisms in the blood and tissues during the progress of septicemia and pyemia, of which the French observer was ignorant. The septic poison, upon the introduction of which into the circulating blood these specific fevers depend, usually originates in connection with the putrefying secretions of surgical wounds and injuries, in which minute rod-like and spherical organisms, known respectively as bacteria and micrococci, are always present, and which are considered by many observers as being essential for the production of the infective material. Some writers assert that the bacteria are the active agents in the pathogenesis of septicemia, pyemia, puerperal peritonitis, and allied affections; while others, again, maintain that the micrococci are the important factors. Billroth and Hallier deny that these organisms are distinct; Klebs doubts it; but Cohn, Rindfleisch, and Cheyne affirm that specific differences exist between them. During the past seventeen years, mainly through the exertions of Mr. Lister, the attention of surgeons has been directed to the prevention of the entrance of these schizomycetes into wounds from the surrounding atmosphere, with a view of avoiding decomposition of the discharges, and thereby averting local and general inflammatory processes. That the introduction of these low organisms into the system from putrefying surfaces occasions the septic fevers is strenuously asserted by Pasteur, Lister, Sanderson, Birch-Hirschfeld, Hueter, Koch, and other distinguished observers; but that they are essential to their development is by no means proved. If it be true that microscopic organisms are the cause of the evils that have been ascribed to them, the micrococci must be regarded as being utterly harmless, since numerous examinations of the discharges of wounds treated antiseptically, conducted by Ranke, Volkmann, Cheyne, and others, demonstrate that they almost invariably contain these bodies, and that they multiply rapidly in weak solutions of carbolic acid. Then, again, if the septic poison is a product of the growth of bacteria, and if the septic fevers arise from the direct action of the bacteria on the system, those affections should not be produced by the injection of putrid fluids from which the bacteria have been removed by filtration through porcelain. Numerous experiments of this nature have conclusively shown, however, that the effects of the poison are not due to the organisms themselves. Hence, other investigators have looked for some other infective material, and have concluded with Panum, Bergmann, and Billroth, that there exists in decomposing fluids a soluble chemical product termed sepsin, to the absorption of which septicemia and pyemia may be attributed.

The intimate nature of the poison of septicemia and pyemia is entirely unknown. The probability is that it is similar to, if not absolutely identical with, the poison of traumatic or surgical fever, erysipelas, hospital gangrene, puerperal fever, and kindred affections. Obstetric physicians long ago noticed that a bad form of septicemia is often produced during pregnancy by the presence in the womb of a dead fœtus. The juices of a decomposing child being absorbed by the uterus, and carried into the system, give rise to the very worst form of the affection, characterized by great gastric irritability, high temperature, great restlessness, offensive alvine evacuations, delirium, and excessive prostration, followed, in a few days, by death. It has been remarked, in such cases, that the amni-

otic liquor and the vaginal discharges are often almost insupportably offensive. When such fluids are permitted to enter the system, whether they contain bacteria and micrococci, or are free from these organisms, they must invariably give rise to a septic fever of the very worst form, and this is precisely what the results of obstetric practice have fully established.

To sum up my own views of the nature of the septic poison, I may state that I believe that the infective material is sepsin, or the chemical product of the decomposition of the tissues, and that the schizomycetes, which have been shown to be present in the blood and organs of septicemic and pyemic animals and men, as well as the corpuscles of putrefying blood and pus, act merely as carriers and disseminators of the poison.

Whatever the nature of the poison may be, one thing is perfectly certain, and this is that it is frequently, if not generally, highly inoculable. Of this fact the results of the experiments above referred to, and of surgical experience, private and hospital, afford indubitable evidence. Many lives have been lost from the effects of wounds and punctures in examining the bodies of persons dead of septic affections; and every obstetrician is painfully familiar with the inoculable character of the secretions furnished during the progress of puerperal fever. The poison in such cases often adheres to the fingers and even to the clothing, despite the utmost attention to cleanliness, and is thus readily carried from one person to another.

The poison gains admission into the system through the lymphatics and the veins, but more especially through the former vessels, and its absorption is effected most readily when the putrid fluid is in contact with a fresh wound, or with a serous or synovial cavity. A point of great practical interest is that healthy granulations, in which most careful examinations have failed to discover the presence of lymphatics, afford a decided protection against septic absorption; but if they are unhealthy or are destroyed they present a surface which readily admits decomposing fluids.

1. SEPTICEMIA.

From the experiments, principally of German observers, which have been carefully considered by the committee appointed by the Pathological Society of London to investigate the nature and causes of pyemia, septicemia, and purulent infection, and whose report may be found in the thirtieth volume of its Transactions, it appears probable that septicemia includes two distinct conditions, which are known, respectively, as septic or putrid intoxication, and septic or putrid infection.

In regard to the former condition, which may be termed toxemia, experiments upon animals demonstrate that if a lethal quantity of putrefying material is injected under the skin death rapidly follows simply from the effects of the chemical poison termed sepsin. The blood injected into another animal does not set up a similar affection, thereby showing that the poison does not multiply in that fluid; nor does the blood, according to the observations of Koch, contain minute organisms, although it undergoes certain changes, of which the most important are, first, the tendency of the red corpuscles to aggregate into small masses instead of rouleaux, and, secondly, the commencing disintegration of the corpuscles, as shown by the staining of the serum with the blood pigment, and the occurrence of petechiæ beneath the serous membranes. The other post-mortem appearances indicate intense congestion of the gastro-intestinal mucous membrane, and engorgement and softening of the spleen. The clinical phenomena which accompany these morbid changes are elevation of the temperature to $104°$ Fahr., and upwards, with corresponding increase in the frequency of the pulse, unrest, muscular twitching, gravescent muscular debility, oppressed breathing, vomiting, profuse diarrhœa, somnolence, and coma.

In the human subject a mild form of septic intoxication is of very common occurrence in connection with severe surgical injuries and wounds, to which the term traumatic or surgical fever is usually applied. The committee already alluded to consider that the conditions under which acute septic intoxication can occur in man comprise the admission of a considerable quantity of putrid matter, as from one to two ounces, rapidly absorbed from large, irregular recent wounds, from serous or synovial cavities, from large abscesses opening externally by an insufficient aperture, and from the raw surface of the uterus left by the separation of the placenta. After the operation of ovariotomy the conditions most favorable to septic intoxication are all present, and many deaths occurring in the first two days are doubtless referable to it. The conclusions of the committee in regard to the evidence to be looked for as indications of acute putrid intoxication in man are, first, " the presence of a sufficient quantity of septic matter to yield the necessary dose of

the septic poison; secondly, the invasion of the symptoms at a time when decomposition of the discharges has commenced, and before the surface of the wound has become covered by granulations; thirdly, high fever rapidly followed by great depression; fourthly, post-mortem appearances indicative of a tendency to congestion and capillary hemorrhage; and, lastly, the absence of organisms from the blood during life, or immediately after death."

In the second form of septicemia, or septic infection, which may be termed ichorrhemia, the poison multiplies in the system, and a drop of the blood or of the inflammatory discharges sets up a similar process in another animal. The blood, moreover, in addition to changes which are met with in septic intoxication, contains large numbers of bacteria; and the lungs, spleen, and liver are congested. The disease develops more slowly and pursues a more chronic course than acute putrid intoxication, and the symptoms are fever with progressive emaciation and exhaustion. The distinction between the two affections is obscure; but infective septicemia may be suspected to exist when from the small size of a wound it is impossible for a lethal dose of septic matter to be formed in it; and the evidence of infection from one patient to another is conclusive when it exists, as it cannot occur in cases of pure septic intoxication. As the clinical distinction between these two forms of blood-poisoning cannot, in the present state of our knowledge, be accurately made, the remaining remarks will refer simply to septicemia as distinguished from pyemia.

In the majority of cases the signs of septicemia begin on the second day, the disease being ushered in by a marked chill, which is followed by febrile excitement, during which the temperature varies from 103° to 108° Fahr., but rapidly subsides during the succeeding sweating. When the affection assumes a severe type, the more prominent symptoms, in the order of their frequency, in addition to muscular weakness, are delirium, an icteric tint of the skin, dyspnœa, vomiting, diarrhœa, and ecchymoses of the integument. In the milder cases the temperature reaches its maximum of 103° or 104° Fahr., in from two to four days, and then sinks with the development of suppuration, and gradually disappears with the formation of healthy granulations.

Attempts have been made to draw a distinction between septicemia and pyemia by the chills, which are said, as a rule, to be limited to the initial rigor in the former, and to succeed one another in a few hours or days in the latter affection. In septicemia they are repeated, however, more than once in four-fifths of all cases, so that this feature is of no diagnostic value. A high temperature is more characteristic of septicemia, and it does not appear to be the subject of the irregular variations of pyemia, which range as high as 10° or even over 10° or 11° Fahr.

The principal lesions found in patients dead of septicemia are congestion of the lungs, parenchymatous swelling and softness of the spleen and liver, extreme congestion and ecchymoses of the gastro-intestinal mucous membrane, subserous petechiæ, and post-mortem staining of the tissues. The blood is not uncommonly very fluid, and early decomposition is occasionally witnessed. The prognosis of the affection is most unpromising. In the fatal cases, although life is now and then prolonged for three weeks, one-half perish in four days from the commencement of the invasion, and four-fifths in the first eight days. The treatment does not differ from that of pyemia.

2. PYEMIA.

The fact that certain injuries and operations are occasionally followed by the development of abscesses in some of the internal organs of the body, did not escape the attention of some of the older surgeons. Ambrose Paré makes distinct mention of the occurrence; and Pigrai, about the same period, noticed that, during one particular year, nearly every person who was so unfortunate as to have a wound of the head, died of suppuration of the liver. These observations were afterward confirmed by Morgagni, Bertrandi, and Andouillé, and, more recently, by Schmucker, Kern, Klein, Hennen, Larrey, Guthrie, and other military surgeons, as well as by many hospital and private practitioners. Velpeau, however, was the first to investigate the lesion in a really scientific manner, and to institute a thorough and elaborate examination into its etiology, pathology, and treatment.

Although the exciting causes of pyemia are of a very diversified character, the most important, by far, are shock, loss of blood, or depression of the vital powers. As following severe injuries of the head, it was, as already stated, long ago noticed by many of the older pathologists and surgeons, although they failed to offer any correct or even plausible theory of its occurrence. Since attention was first prominently called to it, in

1823, by Velpeau, it has been much oftener observed after compound fractures and dis-locations, lacerated, contused, railway, and gunshot wounds, and amputations of the larger limbs, than after any other accidents.   In lying-in females it is also sufficiently frequent. and is, in fact, a considerable source of the mortality consequent upon the puerperal state.   It has been known to supervene upon erysipelas, carbuncle, periostitis, necrosis, diseases of the joints, injury of the big toe, gumboil, abscess of the throat and middle ear, smallpox, scar-latina, typhoid fever, ulcerative endocarditis, suppurative myositis, and even gonorrhœa. One of the first cases of the disease I ever saw occurred in a young woman laboring under a slight attack of erysipelas of the leg.   On dissection, I found the cause of death to have been a pyemic abscess in the left lung, about the volume of a large almond, filled with aplastic matter, and surrounded by highly inflamed and softened tissue.   No appreciable disease existed in any other part of the body.   The secondary purulent collections so often met with in glanders and dissection wounds evidently belong to this class of affections.   Pyemia occasionally succeeds to the use of the trephine, the extirpation of tumors, and operations on the bones, joints, urinary organs, and bloodvessels.   Sometimes, indeed, apparently the most trifling operation is followed by it.   Many years ago I attended, in consultation, a man who lost his life by blood-poisoning consequent upon bleeding at the bend of the arm ; and a similar case afterwards occurred in my own practice at the Louisville Marine Hospital.   The patient, a colored woman, the subject of chronic disease of the wrist-joint, was bled at the median basilic vein.   In a few days violent phlebitis super-vened, followed by large purulent collections in nearly all the principal articulations, as well as among the muscles of the arm and shoulder, terminating fatally in less than a week.   The injury inflicted in the removal of a small piece of dead bone has been known to cause death by embolic abscesses.   In 1848, I lost a young man, twenty-eight years of age, from pyemia, induced by tying three hemorrhoidal tumors.   Death occurred on the eighth day ; and, on dissection, the connective tissue of the mesorectum was found to be studded with hundreds of abscesses, from the size of a currant to that of a small pea.

Pyemia occasionally follows the suppurative inflammation consequent upon a badly-healed stump, weeks, if not months, it may be, after the amputation, and long after the patient is apparently out of danger.   The discharge, perhaps never entirely arrested, suddenly increases in quantity, the parts become tender and irritable, the constitution is seriously affected, rigors soon set in, and, in short, all the symptoms of blood-poisoning are fully declared.

The disease, now and then, assumes an endemic type.   Thus, in the military hospital at Stanton, during the late war, fifty-nine cases, all, excepting two, the result of gunshot injuries and surgical operations, occurred within a period of twelve months.

No period of life is entirely exempt from this disease.   It has been met with even in children at the breast ; and a case has been reported of an infant, only ten days old, in whose body, the subject of erysipelas, not less than nine large abscesses of this kind had formed, causing death in a short time.   On the other hand, it occasionally occurs at a very advanced age.   Young and robust subjects, however, have appeared to me to be most liable to it, especially after severe railway, gunshot, and other accidents, attended with severe shock and excessive loss of blood.   Wounds of, and operations upon, the veins are very prone to be followed by blood-poisoning.   Pyemia is more common among the inhabitants of crowded cities than among those who enjoy the benefit of pure country air, good wholesome food, and an abundance of exercise and sleep ; it is likewise more frequent in hospitals, almshouses, and other receptacles for the poor, than in private practice ; circumstances of no little interest, both in an etiological and therapeutic point of view.

Unhealthy occupations, exposure, fatigue, loss of sleep, and mental anxiety are powerful predisposing causes of pyemia.   It is asserted by Mounier that during the war in the Crimea not a single case of this disease occurred among the first two thousand amputations, while it was afterward very common in association with gangrene, scurvy, typhoid fever, and other low states of the system.

With regard to the immediate cause of pyemia, the old notion that it is the product of metastasis, or, in other words, that it is due to the absorption of pus from the part originally affected, and to the transportation of this fluid to some other, more or less remote, situation, where it is collected into a focus, and thus becomes a source of new irritation and disease, has still its advocates and adherents.   It rests upon the supposition that the pus corpuscles are admitted, unchanged, into the open mouths of the veins at the seat of the wound, as, for example, the surface of a stump after amputation, and that, being so introduced into the circulation, and pushed onward by the blood, they are finally

arrested in the minute capillaries, which are unable to transmit them, as they do the red particles of the blood, in consequence of their lager size. The mechanical obstruction thus occasioned forms, it is alleged, a new cause of morbid action, which is soon followed by the development of an abscess, or a deposition of pus, and, if the new depots be numerous, by purulent infection. In opposition to this doctrine, it has been contended that pus corpuscles never gain access in this way into the circulation, and that those who profess to have seen them there were deceived by the resemblance which these corpuscles bear to the colorless globules of the blood. Moreover, it has been clearly shown that the injection of laudable pus does not induce symptoms which resemble those of pyemia in any respect, but merely gives rise to a transient fever.

The doctrine that pus, as such, cannot enter the circulation has been completely overturned by the observations of modern pathologists, who have demonstrated the permeability of the walls of the veins and capillaries to colorless blood corpuscles, or their equivalents, pus corpuscles, which would render the view of the direct introduction of pus into the blood as a factor in the production of pyemia, at least plausible. In the event of pus corpuscles—pathologically altered colorless blood corpuscles—finding their way into the blood through the softened walls of the vessels of the inflamed part, it is, however, scarcely probable that they would give rise to the formation of abscesses in the manner described in the preceding paragraph, since the tendency of the commingling of the two fluids would be to the production of a clot or thrombus, which would form, as will be pointed out below, the first link in the chain of morbid action. I have myself no doubt whatever that pus, as pus, may enter the blood, and give rise to septic changes in that fluid, and, further that, under certain circumstances, it may lead to the formation of an initial thrombus, to the retrograde changes in which the phenomena of pyemia are partly due.

Passing over other theories which have been advanced from time to time as to the causation of pyemia, it is evident that under the term pyemia should be included three distinct and dissimilar processes, changes in the blood, the formation of septic thrombi and emboli with metastatic deposits, and the absorption of ichorous or putrid fluids, which may coexist in the majority of cases, and are possibly interdependent. The modifications of the blood consist of an increase in the number of colorless corpuscles, with simultaneous increase of the fibrin. The tendency of these elements is to cohere and to form adherent layers upon the inner walls of the vessels, points which not only favor the occurrence of stasis, but also, by presenting centres of roughness, invite more or less extensive coagulation of the blood. It is in this way that the changes in the blood become one of the causes of thrombosis.

The connection of thrombosis and embolism with the formation of metastatic, or embolic, abscesses is one of the most interesting, as well as one of the most firmly established, facts in pathology. A thrombus or clot may form, in a vein, 1st, in consequence of the retardation or interruption of the current of blood, due commonly either to constriction of the vessel, from the compression exerted upon it by the products of the inflamed perivascular tissues, or to the division of the vessel, as, for example, in an amputation, whereby the flow of blood is completely cut off; 2dly, to inflammation of the coats of the veins themselves, the result of very acute inflammation of the connective tissues around them; and, 3rdly, to projections into the lumen of the vessels caused by small abscesses in their walls, or adherent layers of fibrin and white blood corpuscles, due to leucocytosis, or small offsets of fibrin, which are merely the central ends of thrombi formed in the smaller veins, where they communicate with the branch or trunk affected, or colonies of schizomycetes, which line the larger vessels and project into them in the form of papillae. All of these conditions form starting points for larger coagula, which afterwards increase by the deposition of successive layers of fibrin.

The disposition of a fully formed thrombus will depend upon the quality of the fibrin and the nature of the inflammation. If the fibrin be organizable and the inflammation tend to resolution, the thrombus will be converted into connective tissue and cause simple obstruction; but if the morbid action proceed to suppuration and gangrene, the clot will soften, disintegrate, and break down into a puriform fluid, which, mingling with the fibrinous detritus, excites phlebitis, as shown by thickening of, and the occurrence of purulent deposits in, the walls of the vessel, and the partial destruction of its coats.

The central end of the thrombus generally extends to the nearest collateral branch, where it projects into the main trunk, by the addition to it of layers of fibrin, as exhibited at *a*, fig. 17, from Callender. Under the influence of predisposing causes, most probably the septic condition of the blood, the clot softens, particles, fragments, or emboli are loosened and detached by the current of blood, as at *b*, and carried into the circulation,

until the right side of the heart is reached, whence they pass into the pulmonary arteries, in the smaller ramifications of which, and usually at a bifurcation, they are arrested. At the points of lodgement they excite inflammation, which terminates in suppuration and sloughing of the walls of the vessels and of the parenchymatous perivascular tissues, and, in this way, give rise to the so-called metastatic abscesses. In other cases, the embolus is so large as to deprive a portion of the lungs of their due supply of blood, causing in this event gangrene of the points involved. From these primary pulmonary abscesses venous thrombi form, which, in their turn, reach the left side of the heart; and through the systemic circulation develop similar phenomena in the liver, spleen, kidneys, subcutaneous tissue, and other structures. The explanation of those rare cases of secondary abscesses in organs, when the capillaries of the lungs have escaped, is probably to be found in the hypothesis that thrombi disintegrate into particles or granules, which are so minute as to enable them to slip by the pulmonic system of vessels into the left side of the heart.

Fig. 17.

Formation and Softening of Venous Thrombi.

The third process concerned in the development of pyemia, and that which, in all probability, occasions the disintegration of the thrombi, is a poisoned state of the blood, systemic infection, ichorrhemia, or septicemia, consequent upon the absorption of the ichorous, septic, or putrescent material present in suppurating and gangrenous wounds and in stumps after amputation. Not only may the more watery portion of the noxious secretions enter the circulation, thoroughly contaminating both solids and fluids, and, consequently, effectually undermining the constitution; but, as I previously stated, the corpuscular elements may permeate the walls of the vessels, and by their mechanical action upon the blood, excite the formation of thrombi.

The researches of the committee appointed by the Pathological Society of London, to whose labors allusion is made in the preceding section, render it highly probable that pyemia frequently depends upon a general infective process, which is rapidly followed by the development of abscesses without the formation of thrombi. Thus, of 156 fatal cases, in 58, or 37 per cent., there was no evidence whatever that the abscesses and suppurations discovered in the viscera and elsewhere were due to thrombo-embolic processes. In the remaining 98 cases, on the other hand, the disease could be traced to putrid embolisms. In the latter class the poison does not multiply in the system, and it has not been shown experimentally that the affection is communicable by means of the blood from one animal to another. In view of these facts the committee are disposed to separate pyemia, as they did septicemia, into a non-infective and an infective form, the latter being a specific and a communicable disease, whereas the former does not possess those attributes, but is merely a condition of blood-poisoning from the absorption of septic material from putrefying wounds. The first link in the chain of pyemia from traumatism thus appears to be an altered condition of the blood, attributable to a depressed and enfeebled state of the constitution engendered principally by loss of blood, severe shock, or a tainted state of the atmosphere; the second, the formation of abscesses, which are usually found in connection with thrombosis and embolism; the third, systemic infection due to the absorption of noxious matter.

These views of the causes of pyemia derive the strongest possible confirmation from the experiments of Polli and other observers upon animals, proving, as they incontestably do, that unhealthy pus thrown into the blood produces septicemia with multiple abscesses; and, secondly, that the injection of putrid substances gives rise to a bad form of suppuration characterized by symptoms of typhoid gastro-enteritis. Virchow had previously induced all the conditions of pyemia by the introduction of a piece of putrid fibrin into the jugular vein of a dog.

The prejudicial effects that are exerted by the emanations from the wounds of pyemic patients upon the wounds and constitutions of healthy subjects confined in the same apartments, as, for instance, in the crowded wards of a hospital, are well known to military as well as civil practitioners, and they necessitate the greatest possible care in the management of such cases, in order to prevent the extension of disease. A poison of the most subtle and virulent character is engendered in the foul air thus produced, probably similar to that of hospital gangrene, and exceedingly destructive to all those who are brought under its baneful influence. Under these circumstances schizomycetes are gene-

rally developed in great numbers upon wounds and sores, and, in hospitals, may sometimes be discovered upon the floor, walls, and ceilings.

Is pyemia, as the name denotes, always a result of the admission of vitiated secretions, or of putrescent matter into the circulation? Instances occur, as when the disease complicates typhoid fever, scarlatina, and various other asthenic affections, where the reverse would seem to be the case, and yet, it must be confessed, it is not always possible, even here, to determine whether the individual is entirely free from antecedent suppurative action. It is probable that, under such circumstances, mere disorder of the blood, such as undoubtedly attends the worst forms of these maladies, may be quite adequate to the production of secondary abscesses of a very bad character.

The period of latency of pyemia is commonly very short, not exceeding a few days from the time of the accident or operation giving rise to it. There are cases, however, although they are infrequent, in which a much longer time elapses. In every 100 cases the symptoms appear in the first week in 57, in the second week in 19, and after a fortnight in 24. As a general rule, it may be assumed that the briefness of the period of latency will be in proportion to the shock of the system, the amount of hemorrhage, and the ill state of the patient's health prior to the injury. The time is usually shorter in traumatic than in idiopathic affections, in the latter of which the secondary lesion occasionally does not come on until near the period of apparent convalescence.

The approaches of pyemia are generally very stealthy and insidious; hence the young and inexperienced practitioner is often thrown completely off his guard in respect to the nature of the formidable disease with which he has to grapple. If, for instance, the attack is one consequent upon an amputation, he probably feels concerned to find that the stump gives evidence of being in an unhealthy condition, that it is unusually tender and painful, that it manifests no disposition to heal, and that the discharge is not only profuse, but foul, thin, sanious, bloody, or ichorous. The patient, although not inclined to complain much, is restless and ill at ease, looking pale, sallow, and anxious, as if some serious evil were impending. His pulse is irritable and too frequent, the cheek is marked by a sinister flush, the appetite is impaired, the secretions are deranged, and there is a remarkable increase in the temperature of the body. This prodroma is of short duration, often hardly lasting twenty-four hours. Rigors, more or less violent, now set in, and having continued from fifteen minutes to several hours, are succeeded by excessive reaction, and this, in turn, by profuse sweats, often completely drenching the surface and even the body clothes. These rigors may return twice or even thrice in the twenty-four hours, or they may come on at regular periods, not unlike the paroxysms of an intermittent fever, for which the unwary sometimes mistake them. Their severity is not always the same; cases occur in which they are replaced, as it were, by chilly sensations, alternating with flushes of heat, and not unfrequently lasting for several days together. In 27 per cent. of all instances they are absent altogether, and when this happens they are replaced by profuse sweating. In whatever manner this outbreak displays itself, the disease at once assumes a more bold and decisive character. The skin and conjunctiva exhibit a well-marked icterode appearance; the features are shrunken and withered, the nose being pinched and the eye sunk in its socket; the pulse is small, feeble, and frequent, usually ranging from 100 to 120, although it may reach nearly 200; the breathing is accelerated, ranging from 40 to 50 in the minute, and performed with unusual effort; the tongue is hard, dry, and brown; the thirst is urgent; the sleep and appetite are interrupted; the bowels are irregular, being at one time relaxed, and at another constipated; the stomach is irritable and nauseated; the urine is high-colored and scanty; the extremities are cold; the mind wanders; and the body is often racked with excruciating pain, especially in the joints and muscles, which are not unfrequently exquisitely sensitive to the slightest touch. Occasionally the patient complains of severe pain in some internal organ, to which he refers all his principal suffering. Cough is sometimes present, and is then generally dependent upon more or less serious lesion of the pulmonary tissues, or of the lung and pleura. As the disease progresses, red blotches, swollen, and excessively painful, appear upon the larger joints, and serve as the forerunners of approaching suppuration in their interior, as well as in the tissues immediately around them. Similar marks occasionally occur in the course of the principal veins and in the situation of some of the muscles, particularly the deltoid and pectoral. In some of the more obscure forms of pyemia, the chief evidence of the disease is an eruption of the skin, as the erythematous, vesicular or pustular, or an erysipelatous condition of certain portions of the surface, very liable to be mistaken for some other affection.

There is always in pyemia a notable increase in the temperature of the body which, at

the commencement of the chill, rapidly and constantly rises, and attains its highest point at its termination, when it may reach even 108° Fahr. It is, however, subject to irregular variations, which range over 10° or 11° Fahr. During the sweating stage the temperature again falls to its former level.

The symptoms, long before the disease has reached this crisis, are of a typhoid character, the whole system seemingly laboring under the depressing influence of a deadly poison. The downward tendency is rapidly progressive; the machinery of life moves alternately to and fro; the pulse becomes more and more feeble; the respiration is frightfully oppressed; the body is remarkably emaciated; and the patient lies in a comatose condition, from which he is destined never to awake. This, however, is not uniformly the case; for the instances are not infrequent, where the mind retains its consciousness almost to the last. The average period at which death occurs, after the disease has fairly commenced, varies from ten days to a fortnight, the minimum being a few days, and the maximum, as nearly as can be determined, about three months. In every 100 cases, 42 die in the first week, 30 in the second week, 20 in the third week, and 8 after the thirtieth day. Of the more prominent symptoms the most common, in the order of their frequency, are rigors, delirium, vomiting, diarrhœa, rapid emaciation, and jaundice.

Although there are, strictly speaking, no pathognomonic symptoms of pyemia, it is seldom that any one who has ever seen a case of this disease, or who has made himself thoroughly familiar with its history and progress, can possibly confound it with any other complaint. Its very mode of invasion generally sufficiently stamps its true character. The sudden, violent, and unexpected rigor, usually followed by copious sweats; the extraordinary increase of temperature; the unhealthy character of the suppurating sore or wound, if any exist; the icterode and shrunken state of the features; the rapid supervention of typhoid symptoms; the great mental anxiety and excessive restlessness; the horrible aching pains in the joints, limbs, and other regions; and, lastly, the rapid abduction of the fat, leaving the body in a wasted and emaciated condition, far beyond what occurs in almost any other affection, excepting, perhaps, cholera; are signs which, if they do not unerringly mark the nature of pyemia, will always excite the serious suspicion of the attendant, and induce him to scrutinize the case in the most careful and thorough manner. Almost the only disease with which blood-poisoning is liable to be confounded is intermittent fever; but here the distinction is so easily drawn as to render error impossible. Pyemia of the joints has sometimes been mistaken, especially in its earlier stages, for acute articular rheumatism, rheumatic gout, or rheumatoid arthritis. The diagnosis of traumatic pyemia is generally less difficult than that of the idiopathic variety, or that arising from internal causes, the violent rigor, the icterode countenance, and the rapid prostration and emaciation being usually sufficiently characteristic of the nature of the complaint.

The dissection of patients dead of pyemia reveals important and interesting changes both in the solids and fluids. Of those affecting the solids, the most constant are abscesses and purulent depots in various organs, cavities, and tissues. The former, generally known under the name of *metastatic*, embolic, or multiple abscesses, are most common in the lungs, next in the liver and spleen, and, lastly, in the kidneys, brain, and heart. They sometimes occur in the subcutaneous connective substance, and beneath the peritoneum. In one instance, previously referred to, I found an immense number in the connective tissue of the mesorectum. Their presence has also been detected in the prostate and parotid glands.

Professor Sédillot, of Strasbourg, who has studied this disease with great care, remarks that in 100 cases the lungs would be likely to be affected in 99; the liver and spleen in 1 of 12; the muscles in 1 of 15; and the heart and peripheric connective tissues in 1 of 20. Of 131 cases analyzed by the committee of the Pathological Society, abscesses were found in the lungs in 104, in the liver in 14, in the spleen in 11, in the kidneys in 9, in the brain in 6, in the heart in 3, and in the subcutaneous connective tissue in 6.

Metastatic abscesses vary in number in different instances from one to twenty, thirty, fifty, or even several hundreds. Occasionally, indeed, the surface of the affected organ is completely studded with them, more than a thousand having been observed in a single case, principally in the deep-seated viscera. Their size ranges from a hemp-seed or a pea to a hazelnut, a marble, a pigeon's egg, or even an orange. When very numerous, they are usually proportionately small. In their form they are oval, spherical, or angular. When seated near each other, they are occasionally confluent, like the pustules of smallpox.

The contents of metastatic abscesses seldom consist of well-formed pus; on the contrary, the matter is usually of a semi-concrete consistence, of a dirty grayish, cineritious,

or drab color, and largely intermixed with spoiled lymph. It further differs from genuine or healthy pus in the absence of the true nucleated pus corpuscles, and in the existence of an unusual quantity of oily matter and immense numbers of granular cells, and low organisms. When the abscess is more matured, or when it is of long standing, the contents are more decidedly purulent, but even then there is frequently a very considerable amount of foreign substance, as flakes of fibrin, grumous blood, and the debris of the affected tissues. In pyemic suppuration of the serous membranes, the fluid that is so abundantly secreted by these structures consists mainly of turbid serum, or puriform matter; while in the joints it is of an oily or greasy character, of a pale yellowish hue, and destitute of well-formed pus corpuscles and nucleated cells.

The textures immediately around the abscess may be natural, or variously altered in appearance and consistence. In most cases they are engorged with blood, heightened in color, and more or less softened, if not completely pulpified. The coats of the vessels are inflamed, thickened, and infiltrated with serosity, while their canals are filled with pus, semifluid blood, emboli or fibrinous concretions. The capillary veins and arteries usually participate in the inflammation. The blood always contains an unusually large quantity of fibrin and white corpuscles.

Purulent collections, as a consequence of pyemia, are most common in the chest, being rare in the peritoneum, the arachnoid, and pericardium. The reason of this difference seems to be that the lungs nearly always suffer when there is serious involvement of the system, whereas the abdominal viscera, heart, and brain usually escape.

The joints often suffer very severely. In some of the cases that I have had an opportunity of examining after death, matter was found in nearly all the larger ones, and also in quite a number of the smaller. Very frequently the pus is situated on the outside of the joints, as well as within.

Large collections of purulent fluid sometimes occur in the subcutaneous and intermuscular connective tissue, the result evidently of cellulitis; the veins also occasionally contain a considerable quantity, either lying free in their cavities, or, as is more common, intermixed with the blood in the interior of fibrinous concretions.

The pus that is found in these various localities is of the same nature as the fluid contained in metastatic abscesses, properly so termed, that is, it is imperfectly elaborated, and intermixed with a large proportion of aplastic material. Both in the veins and in the intermuscular connective tissue, it is generally, as just stated, interspersed through fibrinous concretions, coagula, or blood-clots, giving the latter a peculiar appearance, as if they were infiltrated with small specks of lymph, or lymph and pus.

In addition to abscesses and purulent collections, the most common lesions met with in pyemia are parenchymatous swelling of the spleen, kidneys, and liver, congestion of the lungs, and subserous petechiae. Internal congestions are, however, less frequent than in septicemia.

The prognosis of pyemia is most unfavorable; few patients recover, and these, for the most part, remain for a long time in a debilitated and crippled condition, liable to outbreaks of other diseases from the slightest causes. Of forty cases, mostly gunshot fractures, treated at the Lettterman Hospital after the battle of Gettysburg, not one was saved. Of 150 cases analyzed by Dr. William S. Savory, of London, 26 recovered, but this is an unusual percentage. The fatal character of the disease is well illustrated in the cases that occurred in the Stanton Hospital, fifty-nine in number, of which, according to the statement of Dr. Lidell, only three recovered, affording thus a ratio of mortality of nearly 95 per cent. Most of the patients died before the tenth day, and two in less than forty-eight hours, only one surviving a month. As already stated, death usually occurs within the first fortnight of the attack, apparently from the severe exhaustion consequent upon the excessive pain and obstructed circulation, so conspicuous in this affection. A return to health is generally announced by the presence in the urine of an unusual quantity of lithic acid and by the gradual subsidence of the graver symptoms.

Treatment.—In the treatment of pyemia the leading objects should be, first to remove the exciting cause of the disease; secondly, to eliminate the poison from the system; and, thirdly, to support the constitution, in order to enable it, if possible, to shake off the toxical influence under which it is so plainly laboring.

If the disease has been induced by an accident or operation, attended with an open, suppurating surface, much may be done, in many cases, by the promotion of cleanliness and the use of antiseptics, to prevent further mischief from the ingress of purulent fluid. This object is best attained by diligent, almost incessant, attention to the dressings and to the position of the part, the former being frequently changed, and the latter so arranged

as to favor the escape of the secretions as fast as they are poured out. Detergent lotions are often serviceable, especially if they contain chlorinated sodium, carbolic acid, or chloride of zinc, but care must be taken that they are not so strong as to irritate; and it will be well, particularly if the surgeon has to deal with a foul stump, to throw them freely upon the parts with a large syringe, as this exerts a much better and wider influence than the less efficient irrigation with a sponge. It will also be advantageous to keep the dressings constantly sprinkled with the chlorides, both with a view of allaying fetor and of purifying the air of the apartment, which must be frequently renewed by opening the doors and windows.

To prevent the further ingress of purulent fluid into the system is not so easily accomplished. If the surface is not too extensive, the best remedy will be the officinal solution of acid nitrate of mercury diluted with four to ten parts of water, applied rapidly and freely with a mop, the intention being not so much to produce an escharotic as an alterant effect, thereby inviting a rapid change in the action of the capillary vessels and an abundance of exudation matter, so as to close up the mouths of the vessels, and cause consolidation of the affected tissues generally. When the vessels are large and patulous, they may sometimes be closed by well-regulated methodical compression. The actual cautery, recommended by the French surgeons for sealing the suppurating surface, should never be employed, unless it be drawn over the parts, previously well wiped, in the most careful and considerate manner.

To neutralize the poison of pyemia, or to render it inoperative, is an object of vital importance in the treatment of the disease, and yet, if such a remedy exist, it remains to be pointed out. The hyposulphites of sodium, potassium, and ammonium seem to have yielded good results in some cases, in the hands of Polli, T. Spencer Wells, Dr. Walter F. Atlee and others, and they are worthy of further trial, as they exert a direct influence upon the blood and the tissues during the time that it is necessary to convert them into sulphates, the form in which they are eliminated from the system. To produce the desired effect, the medicines should be given in large and sustained doses.

The third and last indication is best fulfilled by stimulants and tonics, as brandy, wine, ammonia, camphor, iron, and quinine, with animal broths, and other suitable means of support. Opiates should be given freely to allay pain and induce sleep. The recurrence of rigors, or chilly sensations, is most readily prevented by quinine and morphia, the dose of the former being not less than ten grains to one-third of a grain of the latter, every four or six hours, until a decided impression has been made upon the system. No benefit can accrue, under such desperate circumstances, from administering these articles in smaller quantity, as they only serve to tease the system, and to permit the play of morbid affinities. The irritability of the stomach, so often present in pyemia, is generally best controlled by sinapisms, abstinence from drink, the use of ice, and the exhibition of aromatic spirits of ammonia, champagne, or lemon-juice neutralized by bicarbonate of potassium. Bromide of potassium, either alone or in union with hydrate of chloral, often acts very beneficially under such circumstances. When dependent upon the lodgement of bile, or vitiated ingesta, a gentle emetic may be of service, as ground mustard and common salt. Active purging must be avoided.

Inflammation of the joints and muscles must be treated with soothing measures, as warm medicated lotions and cataplasms, aided by the frequent application of iodine. If abscesses form, evacuation must be afforded by early and free incisions, the opening being made in such a manner as to prevent accumulation and bagging of fluids. Determination to internal organs, as the lungs, heart, spleen, and liver, must be counteracted by dry cupping and blistering. The secretions, generally so much disordered in pyemia, should be corrected with blue mass or calomel, not carried so far as to provoke ptyalism, as this could not fail to prove prejudicial.

Bleeding, both local and general, is invariably inadmissible in all diseases attended with blood-poisoning. The system, oppressed and borne down by the toxical influence, needs all the support it can derive from this fluid; the whole current, it is true, is vitiated, and its vitality greatly impaired, but, although this is the case, no sensible practitioner would attempt to improve the condition of the affected part by such a procedure. Good nourishing food and drink, with invigorating medicines, alone can be confided in under such circumstances, when the loss of even a small quantity of blood would inevitably hasten the fatal crisis.

When a marked tendency to hemorrhage exists, in consequence of a dissolved and broken-down state of the blood, the most suitable remedies will be some of the preparations of iron, especially the tannate and tincture of the chloride, the former in doses of

five to ten grains, and the latter of twenty to twenty-five drops, every three or four hours. The same remedies, either alone or combined with ergot and atropia, will generally answer for arresting the copious sweats so often present in the different stages of pyemia. Sometimes acids, as the nitric and sulphuric, may advantageously be exhibited, with a view both to their tonic and to their antidiaphoretic effects.

Throughout the whole treatment, great attention must be paid to cleanliness; the bed and body clothes should be frequently changed, the surface of the patient sponged with tepid salt water, or weak chlorinated washes, and the apartment constantly ventilated, fresh air being more essential to recovery than all other means combined. In all cases the most rigid observance of hygienic measures will be required to insure ultimate restoration. Convalescence will always be tardy, and the slightest exposure, fatigue, or irregularity of diet will be certain to endanger life.

SECT. VI.—HEMORRHAGE.

A discharge of blood, as an effect of inflammation, is an uncommon occurrence. It may take place in the interstices of the organs and tissues, or upon their free surfaces, and is generally a result of the rupture of some of the vessels of the part, in consequence of the manner in which the blood is sent into them by the heart, at a time when their walls, weakened by the morbid action, are incapable of offering much resistance. It is probable that, when the blood is in a dissolved condition, as occasionally happens in scurvy, typhoid fever, and other low states of the system, the hemorrhage may occur as a product of secretion, or, rather, perhaps as a mechanical transudation, the fluid percolating through the coats of the vessels as water oozes through a bladder, the globules passing off in an altered and disintegrated form.

The fluid may present itself in a pure state; or, as is more generally the case, be mixed with other morbid products, as serum, lymph, pus, and mucus, which may thus essentially modify its properties, if not, in a great degree, mask its character. The quantity of the effused blood varies, in different cases and under different circumstances, from a few drops to a number of ounces. The largest hemorrhages of this kind commonly occur in connection with the serous and mucous surfaces, and the subcutaneous and intermuscular connective tissue, especially in diffuse erysipelas, and in inflammation consequent upon snakebite, in the latter of which the dissolved state of the blood powerfully predisposes to the extravasation. In scorbutic affections, where a somewhat similar condition of the fluid exists, inflammatory hemorrhages are by no means infrequent. Considerable effusions of blood occasionally take place in the air-cells of the lungs and the minute bronchial tubes in pneumonitis. In dysentery, a discharge of blood and mucus is one of the characteristic symptoms of that disease.

Inflammatory hemorrhage rarely comes on until the action of which it is a product has made considerable progress; hence its appearance may generally be regarded as denotive of a higher grade of excitement than a mere deposit of serum, plasma, or even pus. When the discharge is copious, it may, if it do not go too far, prove serviceable in the way of depletion, answering much the same purpose as local bleeding by leeching, scarification, or puncture. In general, however, it is too small to confer any substantial benefit in this way; while, on the other hand, if it be very copious, it may speedily lead if not to fatal exhaustion, at all events to such a degree of depression as to interfere materially with recovery. Besides, it may cause serious mechanical obstruction, as when it is effused into the interstices of organs, thus sadly impeding their functions.

In the treatment of inflammatory hemorrhage reliance is to be placed mainly upon the ordinary antiphlogistic measures, employed more or less vigorously according to the exigencies of each particular case. If the discharge be at all copious, so as to threaten exhaustion, recourse may be had to the administration of acetate of lead in union with opium, and injections of the same article, or, what will be better, of the subsulphate of iron, a substance which possesses a remarkably controlling influence over all kinds of capillary bleeding, whether inflammatory or otherwise. They must, however, be used with great caution, that they may not excite undue irritation. Sometimes the discharge may readily be arrested by cold applications, as cloths wrung out of iced water, and frequently renewed, or by the steady employment of a bladder partially filled with pounded ice, or some refrigerating lotion. When the blood has been poured out into the connective tissue beneath the skin, or among the muscles, and acts injuriously by compressing the capillary vessels, nothing short of early and free incisions will be likely to avail. When the hemorrhage is internal, proceeding from a serous membrane, as the pleura or perito-

neum, the use of sorbefacient remedies is indicated ; but these failing, as they will be likely to do, when the deposit is uncommonly large, evacuation must be attempted with the trocar, although such an operation will generally be extremely hazardous, not to say anything of its inefficacy when the effused blood has undergone coagulation, thus rendering its escape impracticable.

SECT. VII.—MORTIFICATION.

Mortification may be defined to be the death of a part, the rest of the organism retaining its vitality. The word, as now usually employed, is synonymous with gangrene, which was formerly used to denote that state of a part which immediately precedes its dissolution, while sphacelus was employed to signify the complete extinction of life, without any possibility of its recovery. In speaking of the death of a bone, necrosis is the expression generally adopted.

Mortification may be acute or chronic, moist or dry, common or specific, according to the rapidity of its progress, the condition of the dead part, or the nature of the exciting cause. There is really no material difference between acute and moist mortification, or between dry and chronic, and hence these terms may very properly be employed in a convertible sense. The word specific implies the operation of a peculiar virus in the production of the death of a part, as the poison of the rattle-snake, of chancroid, or of malignant pustule.

1. ACUTE MORTIFICATION.

Acute mortification, whether the result of traumatic or idiopathic causes, may occur in all parts of the body, with, perhaps, the sole exception of the heart. There are some organs and tissues, however, which possess this tendency in a much greater degree than others, or which, more properly speaking, are better adapted to withstand its assaults. It may be stated, as a rule, that those textures are most prone to perish, which stand lowest in the scale of organization, or which have naturally a feeble life. Hence the fibrous membranes, tendons, ligaments, cartilages, and bones commonly perish very readily, and often to a great extent. The connective tissue is also very liable to suffer, its areolar structure fitting it in a very special manner for the reception of morbid products, the pressure of which, inducing mechanical obstruction in its vessels, is a frequent cause of mortification in erysipelatous and other forms of inflammation. When the supply of blood is cut off from the skin, by the infiltration of the cellular substance beneath, this structure also dies very readily, notwithstanding its wonderful nervous and vascular endowments. Next in order come the mucous and serous membranes, the lymphatic glands, muscles, nerves, and bloodvessels, the latter of which, especially the larger trunks and branches, generally perish very reluctantly, as is proved by the fact that they often retain their vitality in the midst of the sphacelated parts, as, for example, occasionally happens in malignant scarlatina, attended with mortification of the glands and connective tissue of the neck.

Mortification of the internal organs is very uncommon. In the lungs it is occasionally a consequence of pneumonitis. It is likewise noticed, but still more rarely, in the liver, spleen, kidneys, uterus, and ovaries. The testicle, mamma, tonsils, and salivary glands sometimes perish from the effects of erysipelas, and the prostate from urinary infiltration. Of mortification of the heart no well-authenticated instance is upon record. Gangrene of the brain, from wounds of its substance, although infrequent, is occasionally witnessed.

The *causes* of acute mortification are the same as those of acute inflammation ; whatever has a tendency to produce the one may occasion the other. It is not necessary, therefore, to enter into any minute discussion respecting them. They may be divided, in reference to their character, into five distinct classes: 1. Intensity of inflammatory action. 2. Mechanical obstruction of the circulation. 3. Chemical agents. 4. Defect of nervous energy. 5. Constitutional debility.

I. It has already been seen how *intensity* of inflammation acts in producing obstruction in the capillary vessels of the affected part ; how the blood, rendered adhesive by the increase of fibrin and white globules, attaches itself to their walls, and how these walls, softened and dilated, at length yield under the pressure of their contents, which are often, in consequence, extensively effused into the surrounding tissues, thus materially aggravating the local trouble. As the disease progresses, the capillary engorgement rapidly augments, the blood becoming more and more stagnant, and there is also almost complete suspension of the nervous fluid. In short, the greatest perversion of structure and func

tion exists, the part is in an utterly helpless condition, circulation and innervation are entirely at a stand, and death, already actively engaged at the focus of the inflammation, soon accomplishes its work.

Mortification from intensity of action generally advances at an alarming rate, a large amount of tissue, and sometimes even an entire limb, perishing in the course of twenty-four hours from the commencement of the process. Some of the most characteristic forms of this species of gangrene are met with in compound fractures and dislocations, in lacerated, contused, railway, gunshot, and poisoned wounds, in burns and scalds, in carbuncle, and erysipelas, in which the tissues often succumb under the resulting inflammation with amazing rapidity. Hence, such cases, of which fig. 18 affords an excellent illustration, are generally said to be acute ; and, as the parts are always inundated with fluids, the term " moist" is also often used to designate them.

Fig. 18.

Acute Mortification, Rapid in its Progress, and attended with much Swelling and Moisture.

II. Mortification from *mechanical obstruction* of the circulation may be caused by direct injuries to the arteries, or indirectly through disease of the heart, interrupting the flow of blood to the part. Ligation of the femoral artery for the cure of aneurism of the popliteal, is occasionally followed by mortification of the foot and leg ; and a similar accident sometimes happens from the pressure which a tumor of this kind exerts upon the terminal branches of this vessel. The circulation being thus impeded, inflammation, generally of a very active kind, is liable to be awakened, which soon overpowers the affected tissues. Laceration of the principal artery of a limb often results in the death of the structures which it supplied with blood. Disease of the valves of the heart, leading to vascular engorgement of the feet and legs, along with œdema of the subcutaneous connective tissue, not unfrequently produces similar effects. Tight bandaging, pressure of the body from protracted decubitus, and inordinate constriction of the bowel, in strangulated hernia, are so many causes of mortification from interruption of the circulation.

Gangrene is sometimes produced by obstruction of the arteries by *emboli*, either detached or adherent, or detached clots. Instances of cerebral gangrene, from this cause, have been witnessed by different observers ; and Paget has collected the particulars of seventeen cases in which it gave rise to mortification of the lungs. The influence of the puerperal state in favoring the formation of fibrinous concretions has long been familiar to pathologists. Gangrene of the extremities from detached cardiac clots, or emboli, is sufficiently common. A very interesting case of this form of mortification was kindly shown to me some time ago by Dr. James H. Hutchinson, of this city, in a girl, eleven years of age, who had long been affected with disease of the heart, attended latterly with considerable anemia. Gangrene of the foot and leg set in early in March, and terminated fatally on the 13th of April following, a line of demarcation having previously formed two inches below the knee, and the foot dropped off near the ankle. The limb, at first of a mottled, livid aspect, ultimately became perfectly dark, and was all along the seat of the most intense pain. The heart was found to be dilated and hypertrophied, the mitral valve greatly contracted, the left auricle distended with an old grumous clot, and the right common and external iliac arteries completely obstructed by a firm concretion.

Embolism occasionally induces mortification with astonishing rapidity, as in a case, communicated to me by Dr. Leonard, of a child six years old, who, while seemingly in good health, was suddenly seized with excessive prostration, accompanied with delirium, unconsciousness, and great depression of the temperature of the whole body. In a short time the left leg became livid, and the next morning the foot was found to be dead as high up as the ankle, the surface being black, dry, cold, and insensible. At the end of a week

a line of demarcation began to appear, and, amputation being performed below the knee, the case resulted in a good recovery.

Gangrene from embolism sometimes arises during the progress of typhoid and other fevers. In a case reported to be by Dr. Edward North, the patient, a lad, twelve years of age, while convalescing from an attack of the former of these diseases, was suddenly seized with mortification of the foot, which gradually extended to the leg, along the course of the anterior tibial artery to within four inches of the knee. After amputation of the limb, the cause of the mischief was found to be a clot completely occluding the popliteal artery. A similar case has been communicated to me by Dr. T. H. Andrews. Dr. Walter F. Atlee attended a woman, forty-eight years of age, who, while apparently in sound health, was seized with thrombosis of the femoral artery, ending in gangrene of the leg, followed by death on the sixth day from the attack.

Mortification occasionally arises from obstacle to the return of venous blood. The occurrence is most common in the lower extremities as an effect of valvular disease of the heart, and is generally preceded as well as accompanied by great œdema. When the morbid action is unusually severe, the skin is of a dull red, purple, or livid aspect, from congestion of the subcutaneous vessels, pits freely on pressure, and is the seat of a burning, throbbing pain. Vesicles, of variable size and shape, filled with turbid serosity, form upon the inflamed parts, and, upon bursting, the exposed surface is found to be of a dark red or brownish hue, partially, if not completely, devitalized, cold, and insensible. The mortification usually occurs in small, superficial patches, particularly over the tibia and about the ankle, the skin eventually dropping off in pale, grayish, or ash-colored sloughs.

The sudden loss of a large quantity of blood, in a person of intemperate habits or depraved constitution, sometimes induces mortification. A drunken man, whose case has been reported by Sir B. C. Brodie, was seized, soon after having been bled to an inordinate extent, with gangrene of both feet, doubtless due to embolism.

III. The influence of *chemical agents* in producing inflammation and mortification is exemplified in various ways. The contact of the alkalies and acids, if very slight, will generally cause merely a rubefacient effect; if more severe, it will induce vesication; while in its worst form it will occasion instantaneous destruction of the tissues. Heat and cold act very much in the same manner. In all these cases life is destroyed, either by the primary impression of the chemical agent, or by the violence of the resulting inflammation. In persons of feeble organization, especially, in young children impoverished by starvation and disease, the application of a common blister is often followed by extensive sloughing; and a similar effect is occasionally witnessed as a consequence simply of the protracted retention of a mustard plaster. The infiltration of urine in the connective tissue of the perineum often produces wide-spread gangrene of the scrotum; and portions of peritoneum sometimes perish from the contact of bile and feces.

Although nothing definitely is known of the nature of animal poisons, it is highly probable that they induce inflammation and gangrene much in the same way as the acids and alkalies. Some of these poisons are the product of a peculiar secretion with which the animal is provided as a means of defence; others, on the contrary, appear to be developed by a peculiar septic action, which is particularly strong during the last moments of life, and for a short time afterwards, before the tissues have undergone much decomposition. However generated, their entrance into the circulation usually awakens a peculiar form of inflammation, which not unfrequently terminates in the death of the affected structures; often with extreme rapidity, as, for instance, in snake-bite, chancroid, and malignant pustule.

IV. Defective *nervous power* is an occasional cause of mortification. A palsied limb, for example, is much less capable of resisting the influence of ordinary physical agents than a sound one, and, when inflamed, the morbid action is much more liable than usual to terminate in mortification. In apoplexy and injury of the spinal cord, attended with lesion of innervation, the most trifling puncture, nay, even the application of a blister, is sometimes followed by the death of the part. The occurrence of bad bed-sores, from the same cause, is a matter of daily observation. The division of the peroneal nerve, in the removal of a tumor of the leg, has been succeeded by mortification of the small toes; and Magendie, long ago, ascertained that, if the ophthalmic branch of the fifth pair of nerves be cut within the cranium, the resulting inflammation will end in sloughing of the cornea.

V. The occurrence of mortification from *general debility* is well illustrated in typhoid fever, scarlatina, measles, smallpox, and scurvy, as well as in other states of the system, attended with loss of innervation, and an impoverished condition of the blood. During the progress of these diseases, local inflammation, however induced, is extremely liable

to assume a bad type, and to terminate finally in mortification. In typhoid fever, extensive sloughs often form upon the hips and the sacrum, despite all the attention that can be bestowed upon the patient in warding off pressure ; and in scarlatina and other eruptive maladies, mortification of the neck and throat is by no means uncommon from an inflammation, which, ordinarily, would readily resolve itself in a few days, but which, now that the system is exhausted by the operation of the peculiar poison of these affections, is promptly followed by the death of the part. Inflammation of an organ, set up immediately after the occurrence of profuse and debilitating hemorrhages, is very liable to eventuate in the same disastrous manner. Mercury given in low states of the system, to the induction of ptyalism, often leads to violent sloughing of the gums and cheeks, and to necrosis of the jaw and teeth, followed by the most horrible disfigurement of the features.

A form of mortification of the jaws has long been known among operatives engaged in the manufacture of lucifer matches, from the pernicious effects of phosphorus. How this substance produces this result is still a mystery. It is supposed by some that it makes its impression locally ; by others, that it acts through the constitution, in the same manner very much as mercury.

When acute inflammation is about to terminate in mortification, there is generally a sudden aggravation of all the previous symptoms, both local and constitutional. The pain and sensibility become more keen and intolerable, the redness assumes a more vivid aspect, the swelling and tension materially increase, effusion is unusually active, and functional disorder is at its maximum. If sores or wounds exist, all discharge generally ceases. Along with these local phenomena, there is marked augmentation of the constitutional trouble ; the fever is excessive, the pulse is frequent and often quite strong, the thirst is intense, and there is great restlessness, commonly with more or less delirium. The type of the constitutional symptoms exhibits much diversity. In young and robust individuals it is generally of a sthenic character, or denotive of strength ; but, when the disease has been unusually violent, or the system has sustained a serious shock, whether from the present attack, or from previous suffering, it is commonly indicative of prostration, the tongue and mouth being dry, the pulse frequent and feeble, the stomach irritable, and the surface bathed with cold, clammy perspiration.

The complete cessation of vitality, in mortification of an external part of the body, is denoted by the livid, black, or mottled discoloration of the skin ; by all absence of heat and sensibility ; by a peculiar fetid or cadaverous odor ; and by more or less crepitation, from incipient decomposition. Immediately beyond the seat of the mortification the ordinary phenomena of inflammation are notably visible ; the surface is of a scarlet or purplish hue, hot, dry, tumid, and painful, and the dead and suffering structures are usually insensibly blended, or separated merely by a faint, indistinct line.

The part having actually died, the general symptoms are no longer of an equivocal character, whatever they may have been during the previous struggle. They are now clearly of a typhoid nature, and, consequently, fully denotive of the exhausted condition of the system. The pulse is small, feeble, and one hundred and forty to one hundred and sixty in a minute ; the surface, bathed with cold, clammy sweat, has a yellowish, withered appearance, and exhales a peculiarly disagreeable odor, not unlike that of moist earth ; the respiration is short, hurried, and difficult ; the countenance is pale and shrunken ; the eyes are devoid of lustre and sunk in their sockets ; the nose is thin and pinched ; the lips are incrusted with dark scabs ; the tongue is dry, contracted, and covered with a thick blackish fur ; the abdomen is tympanitic ; and there are frequent twitchings of the tendons, with hiccough and low, muttering delirium. The strength is so much exhausted that the patient, unable to sustain himself upon his pillow, constantly sinks down in the bed ; the stomach is harassed with nausea, or nausea and bilious vomiting ; and towards the last there are often involuntary discharges from the bowels, with retention of urine.

The cause of this depressed condition of the system is probably twofold. In the first place, it may be supposed to depend upon the shock which such an occurrence must necessarily inflict upon the great nervous centres ; and, secondly, upon the absorption of vitiated matter, which, by its union with the blood, contaminates both solids and fluids, thereby incapacitating them for the discharge of their appropriate functions, in short, a poison is developed similar to that in septicemia.

The color of the mortified parts varies in the different organs and tissues. The skin, as already remarked, is usually purple, black, or mottled, while the connective tissue beneath it, in great measure, retains its normal complexion, unless, as sometimes happens, it has been infiltrated with bloody matter, when it will, of course, be of a dark, reddish, or modena color. The aponeuroses, muscles, tendons, nerves, vessels, cartilages, and bones

undergo very little change in this respect. In mortification of the lungs, the color is black; of the brain, grayish or ashy; of the liver, reddish or yellowish. The serous membranes are commonly of a lilac or purplish tint; the mucous, of a black, brownish, or claret, with almost every possible intermediate shade. As a general rule, it may be assumed that the depth of color of the sphacelated structures is in direct ratio to their vascularity and the violence of the antecedent action.

The consistence of the dead part is also variable; in general, it is quite soft, and, as it were, broken down, from the infiltrated condition of the connective tissue and of the inter-molecular spaces of the proper structures of the affected organ. In mortification of the limbs, involving all the compound tissues, the part feels swollen, soft, and crepitant, because it contains both gas and different kinds of fluids, as serum, pus, and blood; but, if the textures be examined individually, it will be found that all, with the exception of the connective, are very nearly of their normal consistence, particularly if there is as yet but little decomposition. In the parenchymatous organs, as the brain and lungs, the loss of cohesion is always very great, the mortified mass being of a soft, pultaceous consistence.

The fetor in mortification is peculiar and characteristic. It evidently depends upon the extrication of sulphuretted hydrogen gas, and is sometimes, as in mortification of the lungs, almost insupportable.

The effects of mortification upon the general system vary with many circumstances; they may be so severe as to destroy life in a few days, or even in a few hours, as occasion-ally happens in the traumatic form of the lesion; or, on the other hand, so slight as to be hardly felt even as a serious inconvenience. In the latter case, an attempt is generally made, after some time, to detach the dead parts from the living, by the establishment of ulcer-ative action, the first evidence of which is the formation of a circle of vesicles, usually filled with

Fig. 19.
Mortification of the Foot and Leg with an Appearance of the Sloughing Process, the Soft Parts being Extensively Separated from the Bone.

a sero-sanguinolent, ichorous, or turbid fluid. Presently these vesicles burst, and then a faint reddish line is observ-able, known as the line of demarcation, which, as it is denotive of the cessation of the gangrene, is always looked for with great anxiety by the attendant. The process, which constitutes a species of natural amputation, seen in fig. 19, often proceeds with considerable rapid-ity, one part separating after another, generally skin and connective tissue first, then muscle, next tendon and aponeuro-sis, then vessel and nerve, and lastly cartilage and bone; the latter being always detached with extreme difficulty, on account of the large quantity of earthy substance which it contains. Owing to this circumstance, several months commonly elapse before the connection is finally severed, and even then the proceeding is anything but surgical, the stump thus made being always badly shaped and but rarely covered with an adequate amount of integument.

The separation of the dead parts is always accompanied with more or less pain, dis-charge, and fetor, adding thus still further to the prostration of the system, and the danger of constitutional contamination. The pain is sometimes excessive, while at other times it is very trivial, depending upon the extent of the morbid action, and the state of the constitution. In general, it is sharp, stinging, smarting, or burning. The discharge, which is often very profuse, is always, at first, unhealthy, ichorous, or sanguinolent, and irritating; by degrees, however, it assumes a more favorable character, and at length acquires all the properties of laudable pus. The fetor is generally sickening, and over-powering; tainting the atmosphere of the apartment, and unless speedily corrected, ex-erting a most prejudicial effect upon the patient. The emanation is, of course, rather from the dead parts, now called a slough, than from the gap, or trough, which lies between them and the living. As the separation progresses, granulations gradually spring up along the raw border, exhibiting the usual appearances of healthy bodies of this kind in other situations, and furnishing an abundance of thick, yellowish pus, which, while it serves to shield them from the rude contact of the air, affords the surgeon excellent oppor-tunity of judging of the nature of the ulcerative action, or, in other words, of the state of the part and system.

While these changes are going on between the dead and living parts, for the riddance of the former, and the benefit of the latter, all the ordinary phenomena of inflammation are plainly visible in the structures above or around the breach, nature being busy in throwing up her walls of defence by pouring out a liberal supply of plastic matter into the meshes of the connective tissue. In this way the surviving structures are solidified and fortified against the ingress of air, and also, at least in some degree, against the absorption of pus and ichorous fluid.

The manner in which the vessels are closed in mortification, so as to prevent hemorrhage during sloughing, is worthy of passing notice. As was before stated, both the arteries and veins possess an astonishing conservative power, by which, at least in many cases, they are enabled to maintain their vitality in the midst of the dead and perishing structures. At length, however, they also yield to the devastating influence, but not before their contents have become thoroughly coagulated and firmly adherent to their inner walls, thereby hermetically sealing their orifices. Hence, no bleeding can occur; and for the same reason there is often no hemorrhage whatever during the artificial section of the part, inasmuch as the clots of blood frequently extend a considerable distance beyond the line of demarcation.

Treatment.—The treatment of acute mortification is conducted upon the general principles applicable to that of inflammation. When this event is about to occur in a person of strong, robust habit, with a vigorous pulse, and a red, fiery, and painful condition of part, the indication is to draw blood by leeching, if not also by venesection, to make free use of depressants, along with a sufficiency of opium to allay pain and quiet the heart's action, and to cover the affected surface with a large blister, to paint it with iodine, or to keep it constantly wet with saturnine and anodyne lotions, either tepid, cool, or cold, as may be most agreeable. When the local action is accompanied with inordinate swelling, punctures, scarifications, or incisions should be made, freely and early, in order to afford vent to effused fluids, to relieve congestion, and to moderate pain and tension. The approach of gangrene may often be averted, certainly materially checked, by the timely use of a blister, large enough to cover in not only the whole of the inflamed part, but also a portion of the healthy skin, and retained sufficiently long to effect thorough vesication. I am satisfied, from observation, that there is generally no more efficient remedy. It is particularly valuable in the idiopathic form of the disease, although it is not without its benefit in the traumatic. I was first led to use it from its great efficacy in erysipelas, where it unquestionably very frequently averts the occurrence of gangrene altogether; and it is well known to the American surgeon that it was a favorite means, in this affection, in the hands of Physick. Cantharidal collodion is a valuable substitute for the blister, as it accommodates itself better to the parts, and is much more prompt in its action.

When mortification has actually occurred, our line of conduct must of course be different from what it is when we are watching its approaches. The symptoms may still be of a sthenic nature, as will probably be the case when the patient is young and robust, and the part invaded is of trifling importance to life. Nevertheless, it will hardly be proper, even then, to indulge in further depletion, certainly not in venesection; leeching may be admissible, and we may perhaps continue, in a moderate degree, the internal use of antiphlogistics; cautiously and warily, however, lest they be instrumental in bringing on premature exhaustion, and thus placing life in jeopardy. When, on the contrary, the patient is feeble, the pulse small and frequent, and the tongue already covered with a brownish fur, clearly denotive of an asthenic state of the system, stimulants and tonics must be employed, and, in fact, every effort made to husband the remaining powers of the constitution. The best remedies then are quinine, tincture of iron, camphor, and opium, alone or variously combined, together with wine whey, pure wine, or what is far better than either, brandy, gin, or whiskey. The diet must be as nourishing and concentrated as possible, so that, while it affords the greatest amount of sustenance in the smallest space, it may not oppress by its weight and bulk. The most reliable articles are beef essence and the different kinds of animal broths, aided, as the appetite and the digestion improve, by tapioca, sago, broma, corn starch, oysters, beefsteak, and poultry, which are then commonly well borne by the stomach. The most potent internal remedies, properly so called, are quinine and iron; full doses of opium, to allay pain and procure sleep; and brandy, in the form of milk-punch. Little, if any, confidence is to be placed in the carbonate of ammonium, musk, castor, and valerian, so much vaunted by some of the older writers, and still occasionally exhibited by modern practitioners; these articles possess no blood-generating power, and rarely do much good even as nervines. The system,

in such a state, requires something more active and permanent, and there are no means so well calculated to fulfil this indication as those just mentioned.

Whatever measures, of a general nature, be adopted, the utmost attention must be paid to cleanliness and ventilation. Sponging the surface several times a day with tepid salt water, or, if there be much perspiration, with a strong solution of alum, will be highly beneficial, if not carried to fatigue ; the body and bedclothes must be frequently changed ; and the windows should either be kept constantly open, or be often raised, in order to secure the admission of pure air, so essential to the healthful reaction of the system in disease.

The object of the local treatment is to allay fetor, which is generally so excessive in acute gangrene, and to promote the rapid separation of the sloughs. The first of these measures is best accomplished by the liberal use of permanganate of potassium, the chlorides, or Labarraque's disinfecting liquid, sprinkled freely upon the parts, as well as upon the body and bedclothes ; the second, by the steady application of fermenting cataplasms, or the warm-water dressing, simple or medicated. The charcoal poultice, formerly so much in vogue in such cases, is now seldom employed, as it discolors and obscures the inflamed surface, and thus conceals its true condition. The ordinary yeast poultice is, on the whole, as eligible an application as can well be made ; where an additional stimulant is required, recourse may be had to camphor water, chlorinated sodium, chloride of zinc, or some of the acids, as the nitric, pyroligneous, and, above all, the carbolic, diluted with from twenty to forty parts of water ; pieces of lint wet with any of these fluids being laid in the gap, and kept in place by the cataplasm.

When the sloughs are tardy in separating, the knife and scissors are employed, with care, of course, in making the dissection, not to interfere with the living tissues, much less with any important vessels. For want of due precaution in performing this little operation, much suffering is sometimes entailed, and I have witnessed several cases in which the patient was absolutely destroyed by it ; for, when the powers of life are greatly reduced by the effects of the gangrene, the most insignificant bleeding and the most trifling shock may prove fatal.

Clearance having been effected of the dead and putrid mass, the next object is to promote the granulating process, by the steady use of emollient and soothing dressings ; aided, if necessary, by weak lotions of acid nitrate of mercury, nitric acid, nitrate of silver, or acetate of zinc, of balsam of Peru, tincture of benzoin, creasote, and similar articles. The system must be supported by suitable tonics, nourishing food, and change of air. As soon as the granulations begin to assume a healthy aspect, as indicated by their florid color, and the thick, yellowish character of the discharges, the healing process will generally progress best under the most simple dressings, serving merely as protectives against friction and rude exposure ; as, opiate cerate, or a light emollient poultice. If the sore be large, cicatrization may be promoted by touching its edges lightly once a day with solid nitrate of silver, and drawing them gently together with adhesive strips. Skin-grafting will often greatly expedite the cure.

In connection with this subject the question of *amputation* necessarily arises. Under what circumstances is this operation necessary or proper ? Should it be performed while the mortification is still progressing, or postponed until it is completely arrested, and a line of demarcation is formed ? These are important points, and they should, therefore, always be duly considered ; for it is the solemn duty of the surgeon to save not only the life, but also, if possible, the limb of his patient. To preserve, not to mutilate, should be the object ; since it is a thousand times more creditable to his skill and judgment to save one extremity than to lop off a hundred, however adroitly this may be done.

In attempting to settle this question, special reference must be had to the nature of the mortification, or the causes under the influence of which it is developed ; for experience has shown that the two forms of the disease generally require different treatment. Thus, in idiopathic gangrene the rule is never to amputate until the surgeon is assured, by the establishment of a circle of demarcation, that both the part and system are in a condition to bear the shock of the operation, and that death has been completely arrested. Even further delay may be demanded, if, upon careful investigation, it be found that the patient is still feeble from the effects of the mortification ; that he looks pale and wan ; that he has a weak and shattered pulse ; in short, that everything is denotive of an exhausted state of his constitution. To amputate under such circumstances would greatly endanger the result, if not positively destroy the patient ; proper allowance must also be made for the loss of blood and the shock which must of necessity follow the use of the knife, both of which, even when the greatest care is taken in performing the operation,

are often most serious. If, on the other hand, the powers of the system are sufficiently active, if there is no apparent contamination of the fluids and solids, and, above all, if nature is making a vigorous effort to arrest the extension of the malady, there is no reason for delay, and therefore the sooner the offensive parts are removed the more likely will the case be to have a favorable termination ; the system is prepared for the emergency, and will soon react from any depression that may ensue from the employment of the knife. Longer delay, in truth, should not be thought of, seeing what pernicious influence the retention of the dead structures must by their putrid and fetid condition exercise upon the system, already weakened to a sad extent by the disease before the tissues were fully deprived of vitality.

From this treatment that of traumatic gangrene is altogether different ; here the extinction of vitality is usually more rapid and extensive, and hence to wait always, or even generally, for the appearance of a line of demarcation, would be virtually, in many cases, to consign the patient to the grave without making an effort to rescue him from the impending danger. When injury of an important artery, nerve, or joint is the cause of the mortification, amputation can hardly be performed too soon ; nothing, certainly, can be gained by delay, which, even in a few hours, may put the case beyond our reach, such, not unfrequently, is the swiftness with which death travels along the affected limb. This is particularly liable to happen in railway, factory, and steamboat accidents, which are so common in this country, and which are often of the most frightful nature, pulpifying the soft parts, laying open large vessels and joints, and literally crushing the bones into atoms. Under such circumstances the judicious surgeon will of course amputate at once, the very moment sufficient reaction has taken place to enable the system to bear the operation ; but instances often occur where the case has been neglected, or ill managed, and where death of the parts has already set in before we are consulted. Now it is precisely in such cases as these that the question will arise in regard to the propriety of immediate action, and much judgment and experience are frequently required to enable us to come to a correct decision. The proper procedure is not to hesitate, if the state of the system is such as to warrant the belief that it will be able to bear the shock of the operation ; but I should certainly refrain if the patient was so far exhausted as to render it probable that he would sink under it. In that event, I should endeavor to rally him by the free use of cordials, as wines, brandy, and quinine, and employ the knife only so soon as a favorable change occurred.

The question of amputation in gangrene from *embolism* is an important one, but, in the existing state of the science, undecidable. It may be stated, however, in general terms, that the operation should be performed without delay when the destructive action is rapidly advancing, provided the patient is free from serious organic disease, and is otherwise in a condition to bear the shock and loss of blood. When the reverse is the case, the proper plan is to wait for a line of demarcation ; and a similar course should be adopted when the mortification is more chronic and is evidently dependent upon the presence of a clot in the principal artery of a limb near the trunk.

2. CHRONIC MORTIFICATION.

There is a form of mortification, in many respects, the very opposite to the one just described, to which, therefore, the term chronic, or dry, may very properly be applied. It is characterized by the remarkable tardiness of its progress, by the absence of humidity, and by the deep color of the skin, which, when the loss of vitality is complete, is as black as charcoal. Mortification from embolism consequent upon ossification of the arteries, the most common cause of the disease, proceeds slowly ; mortification from ordinary embolism rapidly, death frequently doing its work in a few hours, or, at furthest, in a few days.

One of the best types of this variety of mortification is what is now generally known as senile gangrene, from the fact that it is most common in elderly subjects. It is the same disease which was so admirably portrayed, for the first time, by Percivall Pott, of London, under the appellation of mortification of the " toes and feet," and which, for this reason, is still frequently called by his name. It generally begins upon the inside of one of the small toes as a little dark, bluish, or purple speck, not larger, perhaps, than a mustard-seed, which is soon succeeded by a minute vesicle filled with a serous, ichorous, or sanguinolent fluid, and which, bursting, exposes a black surface beneath, perfectly cold and insensible. This spot gradually spreads in different directions until it involves the whole foot, as in fig. 20, as high up, in many instances, as the ankle, or even the middle

of the leg, although, in general, the patient dies long before it reaches that situation. Occasionally, the mortification begins on several toes simultaneously, or in pretty rapid succession; and I have met with examples in which it first showed itself upon the heel and instep. Dr. Charles Marr has communicated to me the particulars of a case in which the disease was confined to the lower and back part of the leg; and in an elderly female under my charge at the Philadelphia Hospital, the gangrene never extended beyond the big toe. However this may be, the part always exhibits a characteristic appearance; it is perfectly dry and withered, cold, insensible, odorless, or nearly so, and as black as charcoal, the limb looking as if it were unnaturally small, as,

Fig. 20.

Chronic Gangrene of the Feet, the Disease being Arrested, and the Parts Undergoing Separation.

in fact, it generally is. During the progress of the mortification, especially if this is somewhat rapid, the skin has occasionally a mottled, purplish aspect, owing to the coagulation of the blood in the superficial veins.

Symmetrical gangrene, as it is denominated, is closely akin to senile gangrene, and is evidently due to embolism of the capillary vessels. It is most common in women between the ages of eighteen and thirty, and originally appears in the tips of the fingers and toes, sometimes in the former, at other times in the latter. It is also liable to occur in the nose and ear. It is generally preceded by a pale and shrunken condition of the affected parts, which gradually change their color to a light blue or purple, and at length become the seat of severe pain. Sometimes the parts feel very cold and numb; vesicles filled with turbid serum usually form. The march of the disease is generally chronic; the bones rarely suffer, and the prognosis, as a rule, is favorable. When the eschars drop off, a clear, healthy sore is exposed, which gradually heals by granulations. The symmetrical development of the disease, in the two halves of the body, its liability to affect both the upper and lower extremities, the comparative youth of the patient, the severe pain, and the remarkable numbness of the affected structures, readily distinguish it from chilblain and senile gangrene. The general health is usually more or less impaired. In a case reported to me by Dr. A. M. Vedder, of Schenectady, in a lady fifty-three years of age, the tips of the index, middle, and ring fingers of the right hand had mortified as the result of embolism of the brachial artery. A similar case has been communicated to me by Dr. P. K. Graybill, of Virginia, the patient being a child, two years and a half old, the subject of a slight attack of scarlet fever, during which both legs and the lower portions of the thighs were seized with symmetrical gangrene.

Whatever its site may be, the disease is usually preceded and accompanied by pain in the toes and foot, darting about in different directions, and liable to nocturnal exacerbations, preventing sleep, and rapidly undermining the general health. The pain, which is of a burning, scalding, or stinging character, is often referred by the patient to the effects of gout or rheumatism, particularly if he was formerly subject to attacks of that nature; it steadily increases with the spread of the disease, and can only be relieved by the free use of anodynes. The dependent posture commonly aggravates it, but, in a case of gangrene of the foot, which I saw along with Dr. Mahlon M. Levis, of this city, in a man eighty-three years of age, the suffering was immensely augmented whenever the limb was elevated even for a few moments. In some instances, the attendant pain is extremely slight. Considerable swelling is occasionally present above the site of the mortification; and cases occur in which the whole of the affected extremity is very œdematous, exquisitely sore, and of a pale rose-color, or marked by an erysipelatous blush.

Although in general this form of gangrene is strictly chronic, an instance is occasionally witnessed in which it spreads with such rapidity as to entitle it to the term acute. The most remarkable case of this kind that I have ever seen, happened in a stout, fat female, sixty-four years of age, a patient of Dr. Coad, of this city, long subject to attacks of gout. The gangrene commenced in the big toe, from which, in less than a fortnight, it spread over the entire foot and lower half of the leg. The parts were as black as charcoal, shrivelled, horribly fetid, and excessively painful.

Well-marked constitutional symptoms attend this complaint, usually from the very first, and sometimes even before there is any local evidence of its presence. They are of an asthenic type either from the beginning, or they soon become so. The pulse is feeble and upwards of one hundred and twenty in the minute, quick, sharp, and irritable. The tongue is coated with a brownish fur, dry, and more or less tremulous; the appetite is impaired; the bowels are costive; the alvine evacuations are fetid; the urine is scanty and high-colored; the sleep is interrupted by pain and frightful dreams; the strength rapidly declines; and the patient gradually dies from sheer exhaustion, the period between this event and the commencement of the attack varying from six weeks to three or four months.

This form of gangrene occurs in both sexes, probably with nearly equal frequency, although it was formerly supposed to be more common in men than in women. It attacks all classes of individuals, the rich and the poor, the idle and the industrious, the temperate and the dissipated. Nearly all the cases, probably altogether a hundred, that have come under my notice, occurred among the middle and poorer orders of the community. It has been conjectured that a gouty and rheumatic temperament predisposes to its development, and cases occasionally occur which would seem to countenance such an idea. Again, it has been asserted that particular modes of life, as indolence and huge feeding, powerfully contribute to its production.

From this variety of chronic mortification few patients recover. In most instances, the disease proceeds steadily, or with an occasional temporary intermission, to a fatal termination from sheer exhaustion of the system. In a case of senile gangrene, in a man sixty-two years of age, recently under my care, the immediate cause of death was opisthotonos. Now and then, as when the powers of life are not too much undermined, the morbid action is arrested, and spontaneous amputation takes place, followed, after long suffering, by recovery. The event is denoted by the establishment of a line of demarcation, immediately above which the surface exhibits a dusky, erysipelatous blush, very different from what usually occurs in ordinary gangrene. The sloughing process is generally attended with severe pain and the most offensive odor.

The cause of senile mortification, as originally suggested by Cowper, an English anatomist, is calcification of the arteries, followed by the formation of fibrinous clots or emboli closing up the caliber of the vessels, and thus mechanically intercepting the passage of the blood. The principal obstruction, as I have ascertained by repeated dissections, occasionally exists at a considerable distance from the seat of the disease. Thus, I have found the occlusion limited altogether to the femoral artery, the popliteal, or the commencement of the tibial and fibular. In most cases, however, it affects also the smaller branches. The concretions generally exist in various degrees of development, from recent coagulation of the blood to complete organization; hence, while some may be easily detached, others are firmly adherent to the sides of the vessels.

The immediate cause of these clot formations is doubtless the interception of the fibrin of the blood by the roughened walls of the arteries consequent upon their calcification, aided by an effusion of plasma, the result of chronic inflammation of the serous membrane, thereby favoring the coagulation and adhesion of the blood.

A form of chronic gangrene of a very remarkable character is sometimes caused by the inordinate use of *ergot*, spurred rye, or secale cornutum. The affection, which has occasionally prevailed endemically, has hitherto been observed chiefly in France, Germany, and Switzerland, in certain districts of which rye bread forms a principal article of diet. When ergot enters largely into the composition of the flour, as it is apt to do in very wet seasons, and is employed for any length of time, it is liable to cause mortification in the remote parts of the body. The attention of the profession was first prominently directed to the subject in 1676, by Dodard, a French physician, and since then it has frequently been noticed by other writers. For a long time doubts were entertained respecting the power of ergot to produce this effect, doubts which were finally solved by Tessier, at the instance of the Royal Academy of Medicine of Paris. He selected for his experiments various animals, especially pigs, ducks, and turkeys, which he fed exclusively upon ergot; he found that most of them died from the tenth to the twenty-fourth day, and that distinct marks of mortification existed in the bodies of all, both externally and internally. Since the poisonous effects of this substance have become so well understood the disease has almost entirely disappeared, and in this country I am not aware that it has ever been noticed in the human subject. It is said, however, to have prevailed extensively among the horned cattle of Chester County, in this State, in 1819, and in the following year in Orange County, New York, from the free use, as was supposed, of a species of green grass, the *poa viridis*, the seeds of which were affected with ergot.

The manner in which ergot acts in producing this disastrous effect has not been explained. It is very singular that its virulence should explode upon those parts of the body which are most remote from the heart, as the feet and legs, and the corresponding portions of the upper extremities, along with the nose, chin, and ears. I am myself inclined to believe that the primary impression of the poison is made upon the blood, rendering it abnormally stimulant and plastic; and the secondary upon the inner coat of the arteries, which, becoming inflamed, thereby intercepts the liquid, and thus leads to the formation of thrombi or fibrinous clots. In a word, there can be no doubt that mechanical obstruction of the vessels is the direct and immediate cause of the gangrene, and, if this idea be correct, we cannot fail to discover the closest analogy between this form of the disease and ordinary senile mortification. It is much to be regretted that Dodard, Noel, Bossau, Gassoud, and others, who have left such admirable descriptions of the external characters of this strange affection, should not have given us any account of its pathological anatomy.

Mortification from ergotism has been observed at all periods of life; it is usually preceded by discoloration, pain, and burning heat, which, subsiding in the course of four or five days, leave the parts cold, dry, hard, insensible, of a uniform black color, and free from fetor. It generally begins in the toes, whence it gradually extends over the foot and leg, until, in some cases, it reaches as high up as the hip. Occasionally it appears simultaneously both in the lower and upper extremities, as well as in the nose and ears. Sometimes the disease is accompanied by considerable swelling and by the most excruciating pain, allowing the patient no rest day or night. The constitutional symptoms vary, being at one time very slight, at another excessive; in general, however, the patient is tormented with fever, thirst, restlessness, and high delirium. Under favorable circumstances ulcerative action is set up, and this, gradually progressing, at length eventuates in spontaneous amputation of the sphacelated structures.

Chronic gangrene is occasionally associated with, if not directly dependent upon, organic disease of the kidneys, especially that form of it which is attended with saccharine diabetes. Cases of this description have been reported by different observers, among others by Marshal de Calvi and Verneuil, who drew special attention to the subject in elaborate memoirs, published, respectively, in 1864 and 1866. The parts generally affected are the lower extremities of old persons; the malady occurring mostly in patch-like spots, and nearly always terminating fatally within a short time of the outbreak of the local trouble. The urine is sometimes both saccharine and albuminous.

Anomalous cases of chronic mortification occasionally occur, of so obscure a character as to render it impossible to refer them to any particular division of the disease, as in the extraordinary instance, recorded in the Philadelphia Medical Examiner, by Dr. Bernard Henry, of this city, the patient, a female, forty-two years of age, having gangrene of all the extremities, from the effects of which she finally died. She was the mother of nine children, was of intemperate habits, and had formerly had syphilis. The disease was preceded by stinging and burning pains in the hands and feet, which, together with the tip of the nose and the skin of the knees, gradually assumed a black, dry, and shrivelled appearance, the gangrene eventually extending beyond the middle of the arms and legs. The only lesion revealed on dissection was some contraction of the left auriculo-ventricular orifice, slightly obstructing the flow of blood into the aorta. The arteries were free from calcification and atheromatous deposits.

Treatment.—Much diversity of opinion still exists among authors respecting the proper method of treatment in chronic mortification; some favoring stimulating measures, while others are the warm and avowed advocates of depletion, as if it were possible in a disease which exhibits such a protean character to lay down any one plan that shall be applicable to all cases. Every case here as every where else, must be managed according to its own peculiar needs. Nevertheless, long experience has convinced me that the stimulant method of treatment is generally the only one that can safely be adopted. I have seen instances where, from the robust state of the individual, and the character of the pulse, no doubt could be entertained about the propriety of the employment, at least to a moderate extent, of antiphlogistic measures, where, indeed, even the lancet and antimony were admissible; but I am quite sure that the instances are comparatively rare, and that, even in them, too much caution cannot be used in their adoption. Nine patients out of ten would be injured by such a course. The symptoms are generally of a typhoid character from the very beginning of the malady, and not only so, but the disease nearly always occurs in old, worn-out subjects, or in persons who have long labored under depression of the nervous, vascular, and muscular powers, and who are therefore ill able to bear such a plan

of treatment. Tonics and stimulants, judiciously administered, and aided by appropriate local measures, constitute the proper means in such cases. Sometimes a "masterly inactivity" is more effective than anything else, the surgeon doing little more than watching the patient, and attending to his diet, bowels, and secretions. But, in general, it will be found that a supporting plan of treatment is absolutely necessary to prevent the system from falling into a hopeless state of exhaustion. Quinine, carbonate of ammonium, and tincture of chloride of iron, with wine, wine whey, or milk punch, and opium, are the most important and trustworthy articles. Anodynes are especially necessary to allay pain, induce sleep, and tranquillize the heart's action, and should be administered in full doses.

Locally, the best remedies are the dilute tincture of iodine, brushed very thoroughly twice a day over the whole of the affected surface, and the use of the bandage, applied with moderate force, and kept constantly wet with a strong solution of opium and acetate of lead, Goulard's extract, or chloride of ammonium. Leeches are usually objectionable, as their bites are sometimes provocative of gangrene, and the same remark is applicable to punctures and incisions. Wrapping the affected parts up in dry cotton is often very grateful, especially as there is generally a feeling of cold in them. By these means the inflammation in the obstructed vessels may now and then be gradually or even promptly arrested, and the further extension of the mortification prevented.

When sloughing has commenced, the same general principles of treatment are applicable as in the acute form of the disease, only that the local applications should, if possible, be still more mild and soothing. The most eligible remedies, according to my experience, are the nitric acid lotion, in the proportion of two to six drops of the acid to the ounce of mucilage of gum arabic, or the opiate cerate, for the ulcerated surface, and cloths constantly wet with a solution of chlorinated sodium for the dead, especially if there be much fetor. As the parts become detached they may be removed with the scissors, but this must be done with the greatest gentleness, as the slightest injury inflicted upon the living tissues is sure to be productive of mischief.

In regard to the question of *amputation*, it is extremely difficult to offer any satisfactory opinion. My belief, founded upon considerable experience, is that we ought scrupulously to follow the practice long ago laid down by surgeons, not to interfere until there is a well-marked line of demarcation; and, indeed, not even then, unless it is evident that there is sufficient strength of the system to bear the shock of the operation. I have, however, seen several cases where amputation was succeeded by the most happy results before nature had made any attempt to cast off the slough, and that, too, under circumstances apparently not at all promising as it respected the powers of the constitution. Whenever surgical interference is deemed advisable, no means should be spared to support the patient with tonics and stimulants, as upon their judicious use the chances of his recovery will, in great degree, depend. When the operation is performed prematurely, or before the system has sufficiently recovered from the exhausted condition consequent upon the gangrenous action, the disease will generally reappear within a few days upon the stump, or death will follow from sheer exhaustion.

At what point should the limb be removed in this form of mortification? Should it be cut off, as is so generally done, close to the line of demarcation? Such a proceeding would only lead to a speedy recurrence of the disease. Instead of this, a remote point should be selected, one, if possible, some distance above the seat of the greatest degeneration of the principal artery of the limb. Thus, it seems to me, as I have long taught, that, when the gangrene is limited to the toes and lower part of the foot, amputation should be performed high up in the leg, and when it affects the upper part of the foot, or foot and ankle, at the inferior third of the thigh. The only objection to such a proceeding would be the greater risk from the operation on account of its closer proximity to the trunk; but this would be more than counterbalanced by the greater safety on account of its distance from the seat of the disease. Some of the cases treated upon this principle by different surgeons within the last ten years have done well; but the number is not sufficiently large to justify us in deducing from them any rule of practice.

The treatment of chronic mortification from ergotism is involved in mystery. There is no remedy, so far as is at present known, the employment of which exerts the slightest counteracting influence upon the deleterious effects of this substance upon the system. Hence the only proper plan of procedure is to manage all such cases upon the general principles just laid down in respect to the treatment of the ordinary forms of the disease. In the symmetrical variety of gangrene, our chief reliance must be upon iron and quinine, with opium and good diet, and the application of slightly stimulating lotions and cataplasms.

SECT. VIII.—HOSPITAL GANGRENE.

Under this name may be described a variety of mortification, or of mortification and ulceration, which often commits great ravages among the wounded in crowded hospitals, in camps, and on board of vessels of war. The disease appears to be much more common in Europe and in the East than in this country, where it is exceedingly infrequent, even in our larger eleemosynary institutions, while in private practice it is almost unheard of. During the late war, however, it was sufficiently prevalent among our wounded soldiers. I place this affection between mortification and ulceration, as it evidently, in many cases, if not in all, strongly partakes of the nature of both.

Although it is extremely probable that hospital gangrene has existed from time immemorial, no distinct and satisfactory account of it appeared until 1783, when an admirable description of it was published in the posthumous works of Pouteau, of Lyons, who had himself suffered from a severe attack of it while resident pupil of the Hôtel-Dieu of that city. Soon afterwards attention was directed to it by Dussassoy, whose treatise was rapidly followed by the tracts of Moreau, Burdin, Gillespie, Leslie, Blackadder, Brauer, and Boggie, to whose joint labors we are mainly indebted for our present knowledge of the affection.

Various names, all more or less expressive of the nature of this disease, have been employed to designate it by different authors. Thus, by Pouteau and some of the earlier writers upon the subject, it was denominated hospital gangrene, evidently in reference to the frequency of its occurrence in this class of public institutions, of which it was at one time the great scourge, both in military and civil practice, particularly the former. Subsequently it was described under the appellations of contagious gangrene, gangrenous phagedena, putrid degeneration, malignant sloughing, or putrid ulcer, camp gangrene, and humid hospital gangrene.

Sporadic cases of this variety of gangrene, more or less severe, are occasionally met with in all large hospitals and other places crowded with sick and wounded, but we no longer hear of that frightful devastation which used to characterize its existence in former times. This happy change is no doubt due to the great attention which the modern practitioner bestows upon ventilation and cleanliness, and the prompt segregation of his patients on the appearance of the malady. According to Mr. Macleod, hospital gangrene was not at all common among the English during the war in the Crimea; it prevailed during the first winter in a mild form at Scutari, but it never became either general or severe, although the barrack hospital of that city was, during the early occupation of the troops, in a very filthy and uncomfortable condition. Whenever any cases broke out, the patients were at once isolated, and sent into wards specially set apart for the treatment of the disease. The French, on the other hand, suffered most severely, owing, as was supposed, to the injury which they sustained during their removal immediately after being wounded to the hospitals on the Bosphorus, and to the manner in which they were crowded together in the wards of those institutions.

Formerly hospital gangrene often prevailed as an endemic, attacking almost every one that was brought within its baneful influence, and thus causing the most horrible mortality. In the Hôtel-Dieu, at Lyons, in the time of Pouteau, several frightful outbreaks of this sort appeared, and such were their ravages that this distinguished surgeon was induced to ask the question, whether hospitals were not an evil instead of a blessing. In 1780, the disease prevailed extensively among the inmates of the naval hospital at New York, some of whom had been sent thither from the West Indies, others from the American squadron, then in port on account of stress of weather. Upwards of two hundred cases occurred, and of these many died; quite a number from the recurrence of gangrene upon the stump after they had suffered amputation. In 1781, the malady committed terrible ravages at the naval hospital on Pigeon Island, St. Lucia. In 1800, it prevailed extensively on board the Prince of Wales, on her homeward passage from Martinique to England; the suffering was excessive, and every little scratch or injury, in whatever manner inflicted, speedily degenerated into a bad gangrenous ulcer. A short time before this, the disease existed in a very severe form at the Cape of Good Hope. Of the horrible ravages, which it occasionally commits at sea, an idea may be formed when it is stated that sixty bodies were thrown overboard by one vessel in thirty-eight hours in her passage from the Bosphorus to the south of France. At Bilbao, after the battle of Vittoria, the mortality from this source was excessive. In the Parisian hospitals, the disease has prevailed, off and on, for many years, often sadly interfering with the results of surgical accidents and operations. In 1847, it appeared in some of the London hospitals, and nearly at the same time in some of those at Edinburgh; in both cities, however, in a mild and transient

manner. In the Philadelphia Hospital I saw cases of the disease, in a more or less severe form, every winter during my connection with that institution, chiefly in old worn-out persons, the subjects of chronic ulcers of the extremities, accompanied with a scorbutic state of the system, brought on apparently by an insufficient supply of vegetables and subacid fruits.

During the late war the disease prevailed more or less extensively in many of our military hospitals. It was particularly troublesome, for a time, at Annapolis, Washington, Baltimore, New York, Louisville, and Frederick, Maryland, after the engagements at South Mountain and Antietam, in September, 1862. At the latter place, it manifested, as has been asserted by Dr. Alfred North, a very decided preference for ulcers of the lower extremities in an advanced state of cicatrization ; with a single exception, no recent wounds were attacked, although numerous operations were performed. In the military hospitals in and around this city comparatively few persons suffered from it, and of these most recovered.

These references are interesting, as showing the occasional epidemic tendency of this disease, and the consequent absolute importance of avoiding the huddling and crowding together indiscriminately of the sick and wounded in large hospitals, camps, and other places, often selected with little judgment, for the accommodation of the poor. There can be no doubt whatever that much, if not the whole, of the immunity enjoyed by the hospitals, infirmaries, and almshouses of this country, is due to the vigilance that is exercised in the sequestration of their inmates, and the great attention that is paid to the cleanliness and ventilation of these establishments ; circumstances which never fail to exert a powerful prophylactic influence upon this and other diseases whose origin and propagation are so closely connected with a vitiated state of the atmosphere and a disordered condition of the blood.

Hospital grangrene shows itself in one of two ways, either as an original affection upon an unbroken surface, or in connection with an abrasion, open wound, ulcer, or amputated stump ; more frequently in the latter than in the former. When the tendency to the disease is very strong, the slightest scratch, sore, or wound may become the means of propagating it, and of producing the most frightful ravages. Several instances have been recorded of the most horrible sloughing occasioned by the accidental inoculation of the bite of the mosquito. When the disease prevails endemically, or even when there is merely such a tendency, no operation, however insignificant, can be performed with any certainty that it may not be followed by hospital gangrene. The stripes inflicted in flogging soldiers have frequently been known to become the seat of the disease in its very worst form. Boils, abscesses, sinuses, fistules, and cicatrices generally, under such circumstances, share a similar fate. It has been noticed that, when hospital gangrene exists as an endemic, it manifests but little disposition to seize upon ulcers of a specific nature, as chancres, venereal buboes, and malignant sores. In its sporadic form, on the contrary, these are the parts which seem to be particularly liable to suffer, the disease often attacking them, apparently, in preference to simple ulcers.

The distinction which has been made by some authorities, of this disease into sloughing and phagedenic, seems to me to be improper, since it is evident that the two affections are merely different grades of the same disorder, the one destroying the tissues in large masses, the other on a small scale, the action by which this is done being strictly identical in both cases. A much more important division is that into idiopathic and traumatic, the origin of the former depending upon constitutional causes, that of the latter upon external injury. In many cases the disease is strictly chronic ; at all events, a disposition to its occurrence sometimes manifests itself for weeks and even months together.

With respect to the *causes* of this variety of gangrene, while some regard it as a strictly local affection, others consider it as having a constitutional origin ; and in this opinion I am strongly inclined to concur, from a careful study of the history of the disease, both from what I have seen of it myself, and from the accounts given of it by different writers. Possessing many features in common with erysipelas and septicemia, it is highly probable that, like these diseases, it owes its origin to a species of blood-poisoning, depending upon a foul, infected atmosphere, operating upon a depraved and enfeebled constitution. It is very certain that the strong and robust are much less liable to suffer from it than those of an opposite state of the system, or who have become exhausted by intemperance, disease, exposure, or want of proper food ; and it is often easy to determine, beforehand, when a great many persons are crowded together in the wards of an infected hospital, which will be likely to be attacked and which to escape, simply from the differences in their appearances. Whether the subjects of hospital gangrene are capable of generating

a poison which, in its turn, can impart the disease to others, by its operation upon the system, is still a mooted point, although an extremely probable one. However this may be, the fact that the malady may be communicated by actual contact of the secretions of a gangrenous sore with a sore of a healthy character, is well established. A very striking circumstance, bearing strongly upon the question of the existence of a distinct poison elaborated during the progress of this malady, has been recorded by Sir George Ballingall, in his Outlines of Military Surgery. Speaking of the disease as it prevailed in a regimental hospital at Feversham, in 1806, he states that, after the endemic had been going on for some time, it was discovered that all the ulcers in the establishment had been washed with one sponge. A different mode of cleansing the sores was immediately adopted, and not a single case of gangrene appeared afterwards. When to this circumstance is added the result of the experiment of Ollivier, who produced the disease in his own person, by inserting matter, taken from an ulcer of the very worst description, into the arm just below the attachment of the deltoid muscle, it is impossible to withhold our belief in the contagious property of traumatic hospital gangrene. The case of Blackadder, who suffered severely from a puncture accidentally inflicted upon one of his fingers in dissecting the stump of a man dead of this affection, is equally strong and convincing.

A scorbutic state of the system, severe shock, loss of blood, and, in short, all depressing influences whatever, probably act as so many predisposing causes of this disease, by lowering the powers of the heart and nervous system, and thereby favoring the operation of the septic poison. Protracted courses of mercury, or exposure to wet and cold during salivation, have often been followed by the disease during its endemic prevalence. In private as well as in hospital practice, it is particularly liable to be induced in young, unhealthy, scrofulous persons, affected with syphilitic ulcers, and weakened by all kinds of privation, especially the effects of cold, and the excessive use of ardent spirits. In the army and naval service of Europe, it formerly often supervened upon severe and exhausting attacks of dysentery, scurvy, and typhoid fever.

When many persons are crowded together, the air of the apartment soon becomes contaminated by the elimination of carbonic acid gas from the lungs, and by the various emanations from the body, the urine, and the feces, so as to render the atmosphere entirely unfit for the purposes of respiration. The deleterious impression is much increased if the patients are laboring under extensive wounds or ulcers, the exhalations from which are often, of themselves, sufficient to poison the system of the stoutest individual.

The period of latency of the poison of hospital gangrene is undetermined. It probably varies in different persons and in different cases, depending upon the previous state of the general health, and the peculiar mode of the infection. In most cases it is short, not exceeding thirty-six or forty-eight hours before it shows its specific effect. When the infection is indirect, a longer time is probably required for the development of the disease than when it is direct, or effected by actual contact of the secretions.

The disease occurs at all periods of life in both sexes, and at all seasons of the year, although it is most common, as well as most virulent, in hot weather.

The *symptoms* are partly of a local, partly of a constitutional nature, the order of their priority being not always easily determined. When it supervenes upon a wound, an ulcer, or the stump of an amputated limb, the appearance of the preëxisting affection undergoes at once a series of the most important changes, completely modifying its whole aspect. The discharge is sensibly diminished, or, perhaps, entirely dried up ; the granulations, if any exist, assume a dark, foul appearance, and are rapidly destroyed ; a large quantity of aplastic lymph, of a dirty grayish color, soon covers the bottom of the sore, the edges of which at the same time become jagged and everted ; the adjacent parts are of a deep purple or livid hue, and the seat of numerous vesicles, filled with sanious or bloody serum ; the pain is constant and excessive, being sharp, biting, or stinging ; the affected structures exhale a horrible odor ; and swelling is both great and threatening. Sloughing now takes place, skin, connective tissue, fascia, and muscle often dropping off in large, livid, putrescent masses, thoroughly impregnated with the most horribly offensive secretions. In the more severe forms of the lesion, the ravages are not limited to the soft parts, but extend to the bones and even to the joints ; the affection, perhaps, rapidly travelling up a limb until it is completely destroyed. Long before this crisis has been attained, indeed generally at an early period, glandular swellings are observed in the groin or axilla, possessing many of the features of pestilential buboes : they usually involve a number of glands, and are always exquisitely tender and painful, thus greatly aggravating the local and constitutional distress. When suppuration occurs, which, how-

ever, is not invariably the case, the discharge is generally abundant and highly fetid, and the resulting ulcer speedily exhibits all the characteristics of the parent sore.

When the disease appears on an unbroken surface, its advent is announced by the formation of little vesicles, or blebs, filled with ichorous fluid, and surrounded by a reddish areola ; both gradually extending, the former soon burst, and thus reveal a dirty, foul slough, which, dropping off, exposes a filthy-looking, excavated cavity, incrusted with a thick layer of adherent, grayish, unorganizable lymph. The parts feel hot and stinging, and there is great swelling, with livid discoloration of the adjacent surface, and a tendency to rapid extension and destruction, the different tissues dying either together or successively, in the same manner as when the disease is ingrafted upon an ulcer or open sore.

As it respects the appearances of the affected structures, hospital gangrene presents three tolerably distinct varieties of form. In one the parts perish, as it were, in mass, and are of a dark red color, very moist, fetid, and infiltrated with putrescent, sanious matter. In a second class of cases, the tissues are converted into a pulpy, diffluent putrilage, or into a dark, brownish, dirty-looking substance, of the consistence of starch, pap, soft cheese, or currant jelly. Finally, there are cases, and these are by no means uncommon, in which, the action being purely ulcerative, the death is molecular, the affected structure melting away, as it were, in an almost imperceptible manner.

The constitutional symptoms are generally well marked, their severity being usually in proportion to the violence of the local disturbance. If the patient, prior to the attack, was tolerably strong and robust, they will probably be of a strictly inflammatory nature, but in any event they will soon lose this type, and assume the asthenic form, which will become more and more distinct as the disease pursues its downward tendency. The pulse will be found to be unusually frequent, quick, and irritable ; the mind peevish, fretful, and desponding ; the tongue dry, and covered with a brownish fur ; the strength much impaired ; and the pain so excessive as to deprive the patient completely both of appetite and sleep. Delirium often sets in at an early period, forming one of the most prominent symptoms.

The *diagnosis* of hospital gangrene is generally not difficult, for there are but few diseases with which it can be confounded. Almost the only affection, indeed, for which it is in danger of being mistaken is scurvy, but a little attention will usually serve to render the distinction between them very evident. The scorbutic ulcer, as it has been named by Lynd and other writers, is remarkable for its fungous, livid, bloody, and fetid character, and the granulations are of enormous size, very soft and spongy, growing with great rapidity, and bleeding copiously upon the slightest touch. The discharge is profuse, and the blood often lies in cakes upon the surface of the sore, from which it is wiped with difficulty ; the pain is trivial, and the granulations, if cut away, are speedily reproduced, generally in the course of a single night. Ulcers of this kind are nearly always attended by serious disease of the gums, which are fungous and extremely vascular, and by hemorrhagic spots in different regions of the body. There is, also, as another striking diagnostic circumstance, an absence of fever, and, generally, also, of vesication. In hospital gangrene, on the contrary, there is always grave constitutional disorder, while the local phenomena are denotive of high vascular action. The ulcer is foul, exquisitely painful, deeply incrusted with lymph, and surrounded by a livid, vesicated surface. The granulating process is speedily arrested, and the sloughing extends in every direction.

The *prognosis* varies with many circumstances. Thus, it is always, other things being equal, more unfavorable when the attack is of an epidemic character than when it is sporadic, and in persons who have been exhausted by previous suffering, privation, or intemperance, than in the young and robust. The extent of the disease must also necessarily exert a material influence upon the progress of the case, the danger being less when this is slight than when it is considerable, and conversely. Serious involvement of the brain, the early occurrence of delirium, or the development of secondary disease in some internal organ, as the lung or liver, always portends evil, and should induce a guarded prognosis. Formerly, hospital gangrene was an extremely fatal disease, the mortality being often in the proportion of one to three of those attacked. In some instances, indeed, nearly one-half perished. Since the pathology of the disorder, however, has come to be better understood, comparatively few cases prevail.

Death may be caused by mere exhaustion of the vital powers from the extreme violence of the morbid action, or from the occurrence of repeated hemorrhages, as when an important vessel is laid open during the sloughing process. In general, the arteries and veins are among the last structures that yield to the devastating influence of the disease, and it, therefore, seldom happens that they are not protected by a provisional clot ; occasionally,

however, nature fails in her efforts, and the bleeding may then not only be profuse but fatal. Finally, there is a class of cases, by no means uncommon, in which, although the suffering is very great, death is apparently caused by an empoisoned state of the system, induced by purulent infection, or the formation of secondary abscesses. The time at which death occurs varies from a few days to several weeks from the commencement of the attack.

Treatment.—The treatment of hospital gangrene was, until lately, very little understood, and the consequence was that an immense number of persons were lost by it. The indiscriminate use of bark and other stimulants, so much in vogue among the army and naval surgeons of Europe, especially those of Great Britain, even down to the time of the late Mr. Hennen and his colleagues in the Peninsular wars, exercised a most destructive influence upon the subjects of this disease. No judgment seems to have been employed by these practitioners, in adapting their remedies to the exigencies of their cases; all were treated alike, and the result was an amount of mortality that was often truly appalling. Dr. Boggie did much to reform this vicious system, by substituting the use of the lancet; but it is questionable whether he did not err by carrying his measures to the opposite extreme. However this may be, it is certain that neither plan is applicable to all cases; but that the management of each must depend upon its own contingencies. The abstraction of blood can, as a general rule, be required only in persons of a comparatively robust constitution, and in the earlier stages of the disease; but even then it should be practised with much caution, lest it lead to fatal exhaustion, or so far damage the system as to prevent it from shaking off, without great difficulty, the morbific influence. The disease, it must be recollected, has an asthenic tendency, often from the very start, especially when it is of an endemic character; and, therefore, any measures calculated to favor this tendency must necessarily exercise a pernicious influence.

Purging and attention to the diet and the secretions constitute important elements in the treatment, and must on no account be neglected. A good dose of calomel and rhubarb, or of equal parts of blue mass, jalap, and compound extract of colocynth, given at the outset of the disease so as to induce two or three large, consistent, alvine evacuations, will often be more beneficial in arresting the morbid action than almost everything else. Subsequently the bowels should be maintained in a soluble condition, without establishing any decided drain upon them, and the utmost care should be taken to restore the secretions, which are always so much disordered in hospital gangrene. Mercury, as a salivant, is to be avoided as a poison.

When the system begins to flag, whether from the overwhelming influence of the attack, or from the neglect of proper treatment, prompt recourse must be had to quinine, iron, wine, brandy, beef-essence, and nutritious broths. The best preparation of iron is the tincture of the chloride, given in doses of fifteen to twenty-five drops, every three or four hours, in some mucilaginous fluid. Quinine is extremely serviceable, and there are few cases, when this stage has been attained, which will not be immensely benefited by brandy, or some other form of alcohol, especially if combined with milk.

But the great constitutional remedy in hospital gangrene is opium, either in substance, or in the form of morphia. It should be given in large doses, generally not less than from two to four grains, every six or eight hours, in union with a diaphoretic, as ipecacuanha, or the neutral mixture. When we reflect upon the excessive pain, irritability, and sleeplessness which so generally attend the severer grades of this disease, it is impossible to place too high an estimate upon the value of anodynes as means not only of insuring comfort to the patient, but of arresting the morbid action.

The diet, especially in the more advanced stages of the disease, should be highly nutritious, and as concentrated as possible. The patient's room should be constantly ventilated, the bed and body clothes daily changed, and the cutaneous surface frequently sponged with tepid salt water, or weak alkaline solutions. The chlorides, bromine, or permanganate of potassium should be freely used. When the disease manifests an endemic tendency, as when it breaks out on board ship, or in the crowded wards of a hospital, the sick should be promptly sequestered, and the apartments thoroughly cleansed.

When the disease is obviously connected with a scorbutic state of the system, the best internal remedies are potassa, in union with lemon-juice, potatoes, water-cresses, oranges, onions, tomatoes, and other fresh fruits and vegetables.

The local treatment should be as gentle and soothing as possible; not rough, irritating, or perturbating. Any vesicles that may exist should be promptly opened either with a needle or with the point of a bistoury, and the whole of the affected surface pencilled over with dilute tincture of iodine, followed by a strong solution of acetate of lead and opium,

either cold or tepid, a cloth wet with it being constantly kept upon the part. If mortification has taken place, the dead substance should be removed without delay, and the exposed surface, thoroughly cleansed and dried, should be freely mopped with a weak solution of acid nitrate of mercury, carbolic acid, nitric acid, sulphate of copper, or perchloride of iron, with a view of changing capillary action and allaying fetor. All strong applications should, in my opinion, be avoided, as they are not only extremely painful, but generally productive of mischief by their tendency to depress the vital powers. If the disease manifests a disposition to spread, and there is, at the same time, excessive suffering, with a marked feeling of tension, scarifications and incisions must be practised, in the same manner and with the same object as in erysipelas.

Attention to cleanliness is of paramount importance. The best mode of effecting this is to cut away carefully all dead substance as fast as it forms with the knife or scissors, to wash the raw surface thoroughly with a weak solution of chloride of zinc, permanganate of potassium, or chlorinated sodium, and, finally, to soak up with cotton or lint every particle of moisture. Unless this be done, no application will be likely to be of any material service in arresting the morbid action.

During the late war extensive use was made, chiefly on the recommendation of Dr. Goldsmith, of pure bromine in the treatment of this affection. It was generally applied by means of a glass test-tube to the whole of the raw surface, previously divested of slough, and thoroughly dried. The parts were then covered with a yeast, cinchona, or port-wine poultice. One application usually sufficed; if a second was necessary, it was not made under several days.

Dr. Hinkle found a favorite remedy in permanganate of potassium well known for its powerful deodorizing, disinfecting, and oxygenating properties. He used it both internally and externally; internally, in doses of one or two grains several times in the twenty-four hours, and externally, as an escharotic, in concentrated solution, applied by means of a camel-hair pencil to the surface of the wound and also to the cuticle for some distance around. The parts were first thoroughly cleansed with Castile soap and water, and afterwards covered with lint soaked in a weak solution of the medicine, the dressing being renewed every three hours. When the wound was deep seated or inaccessible, medication was effected with the syringe. The sloughs usually separated in from four to six days, leaving a healthy sore which soon healed under simple treatment.

Dr. John S. Packard derived great benefit from the employment of powdered white sugar, thickly dusted upon the raw surface, which was then covered with wet lint, confined by adhesive strips and a bandage. The application, which was always preceded by the thorough removal of slough and matter, was found to be extremely useful in checking the morbid action, and was relied upon almost exclusively in the treatment of this affection in several of the military hospitals in and around this city. Buttermilk yielded excellent results, in one of these institutions, in the hands of Dr. Walter F. Atlee; and Professor L. A. Dugas, of Georgia, found nothing so beneficial as tar-water. The application of lactic acid, as suggested by the late Professor Samuel Jackson, of this city, on pledgets saturated with the fluid, and frequently renewed, is worthy of trial. Subsulphate of iron—Monsel's salt—is also an excellent remedy, at once mild and efficient, promptly neutralizing fetor, and rapidly changing the action of the sore. It is a powerful deodorizer and desiccant.

The hot iron, formerly so much vaunted as a remedy in the treatment of this affection by the French and German surgeons, will not be likely to have many advocates at the present day. That the application, especially if it embraces the whole of the diseased surface, may occasionally be beneficial, is unquestionable; but there are so many more efficient and agreeable measures that it may well be abandoned.

Personal experience fully satisfies me that, if care be taken to cleanse the wound properly of slough and sanious matter, which is always poured out in such great abundance in this affection, it is of little consequence whether the application be carbolic acid, acid nitrate of mercury, nitric acid, sulphate of copper, creasote, tar-water, bromine, nitrate of silver, permanganate of potassium, sugar, or buttermilk. A port-wine poultice, or a poultice made of elm bark or flaxseed meal, sprinkled with quinine or cinchona, often answers an excellent purpose, and there are few, if any, articles more likely to prove serviceable than pyroligneous acid. The remedy, however, which I have found most useful is acid nitrate of mercury, freely diluted with water, and carefully applied with a soft mop.

When the mortification is arrested, amputation must not be thought of until there is a decided line of demarcation, with sufficient power in the constitution to bear the shock of the operation. The tendency to recurrence of the gangrene, after removal of a limb,

is sometimes astonishingly great. Salleron, of Lyons, during his attendance upon the hospitals at Constantinople, during the Crimean war, witnessed cases in which the disease relapsed four, five, and even six times, owing apparently to the foul atmosphere of those institutions. As soon as the men were able to bear the voyage, they were sent to France. During convalescence, change of air always proves an important auxiliary to recovery.

SECT. IX.—ULCERATION AND ULCERS.

Ulceration is the molecular death of a part, as mortification is the destruction of a part upon a large scale: in a word, it is death in miniature. At least three distinct acts are concerned in its production: softening, disintegration, and, lastly, removal of the affected tissues as effete and extraneous matter. Antecedently, however, to these acts there is another paving the way for their advent, namely, inflammation, which is always an indispensable accompaniment of the process, whatever its site, stage, or degree. It was formerly supposed, chiefly in conseqence of the influence of the writings of John Hunter, that ulceration consisted essentially in the disintegration and absorption of the suffering textures; hence the general use of the phrase "ulcerative absorption." According to this doctrine, the diseased substance, after having been devitalized, is taken up by the absorbent vessels, and thrown into the blood, to go the rounds of the circulation, and be finally cast off as excrementitious matter. There are numerous circumstances which, at first sight, would seem to favor such a view. Thus, large ulcers sometimes form in a very short time, and yet it is quite impossible, so far as can be ascertained by the most careful scrutiny, to determine what has become of the tissues concerned in their development. If search be made for them in the discharges, they cannot be discovered, since their quantity, however great, is frequently insufficient to account for the loss of solid material. Similar phenomena are witnessed in abscesses of the brain, lung, liver, and spleen, where enormous destruction of the proper substance of these organs often occurs from the accumulating pus, without our being able to explain what has become of it. It might naturally be supposed that the lost tissues were contained, in an altered and disintegrated condition, in the pus, but such a conclusion is disproved by the fact that it is impossible to detect their presence by the most careful examination.

The disease appears under two varieties of form, the open and occult or, as it may not inaptly be termed, the subcutaneous. The first is by far the more common. Of the latter, examples are seen in various kinds of abscesses, sinuses, fistules, Pott's disease of the spine, coxalgia, and other affections, in which the morbid action is carried on beneath the skin, out of sight, instead of upon an open surface.

Ulceration has a remarkable disposition to invade some structures and to shun others. Those which are most liable to its inroads are the dermoid and mucous tissues, the cartilages, bones, lymphatic glands, tonsils, uterus, lungs, and kidneys. The fibrous and serous membranes, muscles, tendons, vessels, nerves, brain, heart, liver, and spleen, together with the salivary, prostate, and thyroid glands, seldom suffer from it. Newly formed parts, as cicatrices and the callus of broken bones, are easily affected by ulceration, especially when, from any cause, there is a depraved and impoverished condition of the system. It is worthy of remark, both in a pathological and practical sense, that this action is much more prone to occur in certain portions of the same structure than in others. Thus, ordinary ulceration of the skin is by far most frequent in the legs and feet, whether because these parts are in a state of habitual congestion, or because they are more exposed to fatigue and accident, is not determined. The disease is extremely rare in the œsophagus, but very common in the pharynx, tonsils, tongue, cheeks, and lips. The same remark is true of ulceration of the stomach and small intestine as compared with ulceration of the colon and rectum. In the genito-urinary division of the mucous system a similar law obtains. Thus, the affection is extremely rare in the urethra and bladder of the female, but very common in the vulva, vagina, and uterus. The male, on the contrary, seldom suffers from ulceration in any portion of the genito-urinary apparatus, except as a result of venereal diseases.

Ulceration is common or specific; common, when it is the result of ordinary inflammation, specific when it is caused by a special poison, as, for example, that of syphilis. In the latter case, the disease runs a peculiar course, and, during its progress, furnishes a specific secretion, capable, by inoculation, of producing a similar action. The ulceration that attends carcinoma is also specific, but the matter yielded is not communicable by actual contact

Ulceration varies in its progress, being sometimes very rapid, at other times very tardy. The circumstances which determine this result are not always appreciable, but, in general, they depend upon the nature of the exciting cause, the amount of the attending inflammation, and, above all, the state of the system. When the action is very rapid, an extent of surface may be destroyed in a few days which cannot, perhaps, be repaired under several months. The process often goes on simultaneously at several points in the same organ or tissue, and not unfrequently in structures of an entirely opposite character.

The causes of ulceration do not differ from those of inflammation, more or less of which, as previously stated, always accompanies the process. They may very properly be divided into predisposing and exciting. The former comprise an impoverished state of the blood, however induced, and, in short, whatever has a tendency to impair the powers of the system. Experiments, performed long ago, by Magendie and others, have established the fact that the protracted and exclusive use of starch, sugar, and other non-azotized articles of food, is capable of producing ulceration of the cornea; and it is well known that the poorer and more ill-fed classes of people are peculiarly subject to ulceration of the skin and mucous membranes. Ulceration of a severe nature often follows upon scurvy and the various kinds of fever, especially typhoid, scarlet, and morbillous, from the exhausting influence which they exert upon the solids and fluids.

The exciting causes may be common or specific, the latter being such as act primarily upon a particular part, as, for example, the head of the penis in chancre, or, secondarily, in the same disease, upon the constitution, in consequence of the absorption of the specific poison. Tubercular, scirrhous, encephaloid, melanotic, and sarcomatous tissue, after having undergone softening, always creates ulceration by its pressure upon the adjacent soft textures, thereby favoring its elimination from the part and system.

The inflammation which precedes and accompanies ulceration varies much in degree, as well as in character. When acute, it is usually marked by the phenomena which ordinarily distinguish it under other circumstances, as discoloration, heat, swelling, pain, and disordered function, and then often spreads with great rapidity, laying waste a large amount of tissue in an almost incredibly short time. When this is the case, the molecular structures perish, as it were, in mass, and not in the slow and gradual manner which characterizes the disease when the inflammation is of a more mild and simple grade. It is to this form of ulceration that the term phagedenic is commonly applied, from a Greek compound literally signifying to eat, feed upon, or erode, the parts around the breach made by the morbid action being rapidly disintegrated, melted down, and cast off, as if they had been consumed by fire, their ashes alone being left as the evidence of their former existence. When the concomitant inflammation is chronic, the ulceration generally advances more tardily, and is also marked by milder symptoms; this rule, however, has many exceptions.

The pain of ulceration is sometimes peculiar, affording thus valuable diagnostic information. Thus, in ulceration of the joints and bones, it is usually heavy, aching, or gnawing; in rupia, hot and burning; in scirrhus, sharp and lancinating, or like the pricking of a needle. Sometimes, again, there is a complete absence of pain, as in common ulceration of the skin, in ulceration of the glands of Peyer in typhoid fever, and in ulceration in tubercular disease of the large bowel. The pain, as a rule, is more severe in the acute than in the chronic form of the disease, and it is then also more steady and persistent. In syphilitic ulceration of the skin and bones, the suffering is often intermittent, the paroxysm usually coming on at night, and gradually disappearing towards morning. Finally, the pain may be of a neuralgic nature, although this is rare.

Ulceration is always attended with more or less discharge of matter, the quality of which is greatly influenced by the nature of the case. Thus, when the attendant inflammation is unusually high, the matter is generally sanious, bloody, ichorous, corrosive, and profuse; a similar fluid is always present in ulceration of carcinomatous growths. When the action is less severe, or tending to restoration, the discharge is commonly somewhat consistent and of a yellowish color, like laudable pus.

The tendency in ulceration is usually towards the nearest surface, an occurrence which is often of great service in the evacuation of abscesses and the discharge of foreign matter. It would seem as if nature availed herself of the operation of this law to economize time, save structure, and prevent pain. If it were otherwise, abscesses would often, if indeed not generally, be emptied in the most tedious and circuitous manner, and at the expense of vast suffering, both local and constitutional. Of the beneficial effects of this law, an illustration is afforded in collections of pus in the liver, which, as a rule, discharge themselves, not through the walls of the abdomen, which are thick, muscular, and resistant,

but through a contiguous coil of intestine, which is thin, proximal, and yielding. In abscess of the lung, the matter usually escapes through a neighboring bronchial tube; when it makes an effort to empty itself externally, it either pours the fluid into the pleural cavity, thus speedily causing fatal inflammation, or it attains its object only after a long and tedious process of ulceration, generally accompanied with great pain and hectic irritation.

When ulceration has continued for some time, it manifests a disposition either to remain stationary, to cease altogether, or to progress in a modified form. Its conduct, in these various particulars, is greatly influenced by internal and external circumstances, as the state of the constitution, the amount of the local inflammation, the nature of the exciting cause, and the effects of remedies. In the skin of the lower extremities, in syphilitic rupia, in the spongy structure of the bones, in the movable joints, and in malignant growths, it often continues for an almost indefinite period, being better at one time and worse at another. When it is about to cease, the accompanying inflammation gradually subsides, the discharges disappear, and, plastic matter being poured out, granulations are formed, by which the breach is finally closed, the process of cicatrization generally, if not always, proceeding from the circumference toward the centre.

In the treatment of ulceration, the great and leading indication is to combat the concomitant inflammation, so as to place the part in a condition for the efficient development of granulations, as it is through their agency that the lost substance must finally be repaired. For this purpose the ordinary antiphlogistic appliances are to be put in requisition and continued until the morbid action has been completely arrested, as will be denoted by the subsidence of the pain, heat, swelling, and redness by which it is usually characterized. When granulations begin to form, only the most mild and soothing measures must be employed, and the sore carefully watched to keep it in a healthy condition until it is perfectly cicatrized. In specific disease, as chancroid and malignant pustule, the most efficient treatment, provided the case is seen in time, before the matter has gained entrance into the veins and lymphatics, is to cut out the part, or destroy it with the actual cautery, Vienna paste, or acid nitrate of mercury.

In ulceration under the skin, or skin and mucous membrane, such as is witnessed in sinuses, fistules, and other diseases, a cure can seldom be effected without the free division of the affected structures; injections, simple and medicated, and systematic compression, however long continued, generally fail; the knife is the most effectual remedy, and its early employment often prevents an immense amount of suffering. General treatment is, of course, not neglected. In most cases tonics and other supportants are required to invigorate the exhausted constitution.

ULCERS.

An ulcer is a breach in continuity of a surface, organ, or tissue, attended with inflammation, and a discharge of pus, ichor, or sanies. The disease, which is of frequent occurrence, is met with at all periods of life, in both sexes, and in all classes of persons, and is often a source of great suffering to the patient, as well of immense trouble and vexation to the surgeon. Its very name carries with it an idea of loathsomeness, and it may well be imagined how much this feeling is increased when, as so often happens, the sore is the seat of foul and offensive discharges, rendering the patient disagreeable alike to himself and to all around him.

There is not, it may confidently be asserted, in the whole domain of surgery, a class of maladies, the pathology and treatment of which are so little understood by the profession generally as those of ulcers. It is surprising what an immense amount of confusion still exists upon the subject even among many of the best and most experienced authors. In examining the various treatises on surgery, in the principal languages of Europe, the reader has little cause to congratulate himself upon the progress that has been effected in this department of the healing art. He looks almost in vain for any positive additions to his stock of knowledge since the latter part of the last century, when Mr. Benjamin Bell published his Treatise on the Theory and Management of Ulcers. The minute divisions and subdivisions, the refinements and absurdities, respecting the nature of these lesions, are, with little variation, substantially reproduced by most of the practical writers of the present day. In studying the literature upon the subject, one is almost forced to conclude that, while every other branch of surgery has experienced the salutary influence of progress, this one alone has remained unimproved and uncared-for. I am, indeed, ready to admit that the nosography of ulcers is much more perfect now than it was formerly;

but who can read their classification, as it appears in most of our modern treatises, and not be struck with its many absurdities and inconsistencies? The catalogue is absolutely appalling, and it must be apparent to the most superficial observer that it comprehends, under different names, diseases which are absolutely and positively identical in their nature; not even constituting, strictly speaking, so many varieties, much less distinct species. Sir Astley Cooper, in his Lectures on the Principles and Practice of Surgery, describes not less than ten forms of ulcers, under the names, respectively, of healthy, languid, inflamed, gangrenous, irritable, sinuous, menstrual, varicose, ungual, and cutaneous, the latter including noli me tangere, and ulcers with thickened, inverted, and everted edges. A more recent foreign author, whose works were at one time extensively circulated in this country, adopts a somewhat similar arrangement. Thus, he treats, under so many separate heads, of the simple purulent or healthy, the weak, scrofulous, cachectic, indolent, irritable, inflamed, sloughing, phagedenic, and sloughing-phagedenic ulcer. The same spirit of classification pervades the works of more recent writers. Why, then, should it be deemed strange that the student should take up the investigation of the subject with doubt and misgiving as to his ability to comprehend it, even in the most superficial manner? No one, however industrious and intelligent, can possibly unravel the mysteries of divisions so minute and so utterly unphilosophical. It would puzzle the most profound pathological anatomist to discriminate between some of these classes of ulcers, as, for instance, between the irritable and inflamed, the sloughing and sloughing-phagedenic. To describe every sore that appears upon the body as a distinct ulcer because it happens to possess slight shades of differences in its external characters, would be as absurd as to describe, in a work on anthropology, every human being as a separate variety of the race because he happens to be a little unlike his neighbor. All inflammatory affections resemble each other, some closely, others remotely, but yet always sufficiently so to enable us to trace out their relations and affinities. The same is strictly true of ulcers; no two cases are ever precisely alike, and yet the most superficial observer may see that they exhibit many traits in common; one may be undermined, incrusted with aplastic matter, and the seat of severe pain, with a foul, sanious discharge, and great discoloration, heat, and swelling of the surrounding integuments; another may have hard and elevated edges, and a glossy, granulated surface, with, perhaps, scarcely any secretion at all, and none of the ordinary evidences of inflammation; in a third case the ulcer may be disposed to spread, its tendency being essentially destructive; in another series, by no means uncommon, the sore has thickened and everted edges, with profuse ichorous discharge, and an inability to furnish reparative material; finally, there may be a varicose state of the veins of the part, a sinus, disease of the adjacent bone, or disorder of the general system, modifying the action of the ulcer, and interfering with its cure. These are, it is true, contrarieties, but contrarieties which are solely dependent upon local and constitutional causes, and which, consequently, are not entitled to be considered as distinct diseases. We might as well say that the varieties of color in ordinary inflammation constituted so many reasons for founding new species of morbid action, when it is obvious that in this, as in the former case, the circumstance is purely accidental.

Assuming that all ulcers are merely so many forms of inflammation with breach of texture and more or less discharge, the most rational classification, it seems to me, that can be adopted, is that of ulcers into acute and chronic, according to the intensity and rapidity of the morbid action. Such an arrangement certainly greatly simplifies the subject, and divests it of much of the mystery and perplexity that have hitherto enshrouded it.

There are two genera of ulcers, just as there are two genera of inflammations, the common and the specific. Common ulcers are such as are produced by ordinary causes, as common inflammations, abrasions, and wounds; specific ulcers, on the contrary, owe their origin to the operation of some peculiar virus, as the poison of syphilis, smallpox, glanders, or malignant pustule. Although the ensuing remarks are more particularly intended to illustrate the various forms of common ulcers, they are also, at least in some degree, applicable to the specific, which, however, will receive special attention in their proper place.

1. ACUTE ULCERS.

The acute ulcer is distinguished by the rapidity of its progress, and the severity of its symptoms, which are those very much of ordinary acute inflammation. The sore usually

begins at a small point of skin, or skin and connective tissue, from which it speedily spreads in different directions until it often covers a large extent of surface. In its form it is generally somewhat oval or circular, but it is frequently very irregular, and instances are met with in which it is of a serpiginous, creeping, or angular shape. When the ulcerative action commences simultaneously at several spots, as occasionally happens, the sore may have a peculiar, sieve-like, or worm-eaten appearance, similar to that of the cover of an old book, or the bark of a tree. Its surface is red and angry-looking, either uniformly, or red at one point, and white at another, owing to the presence of aplastic matter, which occasionally overspreads it completely. When the action is unusually severe, the bottom of the ulcer generally exhibits a foul, greenish, brownish, or blackish appearance, and if, under such circumstances, any plasma is poured out, it is immediately spoiled or washed away by the discharges, which are always thin, sero-sanguinolent, and irritating, possessing none of the properties of laudable pus, such as is furnished by a granulating wound. In regard to the edges of this class of ulcers, they present the greatest possible variety; in general, however, they are thin, rather sharp, and somewhat undermined, or undermined at one place, straight at another, and perhaps everted at a third; in some cases they are very steep and ragged, notched or serrated. Extending from the sore in different directions are occasionally small sinuses or fistulous passages, which thus greatly complicate its character and protract the cure. The parts immediately around the ulcer exhibit all the phenomena of high inflammation, being of a deep red, livid, or purple color, preternaturally hot, painful, and more or less œdematous, from sero-plastic effusions.

The pain of the acute ulcer is frequently a prominent and absorbing symptom; it varies not only in degree but in character, being at one time throbbing or pulsatile, at another sharp or pricking, at another dull, heavy, and gnawing. Its violence is often altogether disproportionate to the extent of the morbid action. Cases have often been under my observation in which, although the ulcer was scarcely as large as a twenty-five cent piece, the pain was so excruciating as to deprive the patient of sleep for days and nights together, and bring on rapid emaciation and hectic irritation. It may be limited to the sore, but in general it is felt over the whole of the inflamed surface, and is usually worst at night and in damp states of the atmosphere. Posture also commonly aggravates it, being more severe when the part is dependent than when it is elevated, although occasionally the reverse is true, even when the sore is quite large.

Along with these phenomena there is generally considerable constitutional derangement, manifesting itself, not so much in febrile commotion, as in an irritable state of the system, and in disorder of the digestive organs. The patient feels unwell rather than sick; his head troubles him; his appetite is vitiated, or temporarily arrested; the tongue is coated, and there is a bad taste in the mouth, especially in the morning; the bowels are inclined to be constipated; and the urine is scanty and high-colored. When the ulcerative action is rapid and extensive, there is frequently more or less fever, with thirst, restlessness, loss of sleep, and excitement of the pulse. Disorder of the secretions is generally a prominent symptom in these cases, especially of the liver, uterus, and mucous follicles.

An impoverished state of the blood, however induced, habitual intemperance, excessive indulgence at table, mental anxiety, exposure to cold, and the various eruptive diseases, may be enumerated as so many predisposing causes of the acute ulcer. Nervous, irritable, and plethoric persons, especially old dram drinkers, are its most frequent subjects. Both sexes are liable to it; but men, from their greater exposure and hardships, suffer much more frequently than women. It is rarely met with in the higher circles of society, and in very early life.

An ulcer may be acute from the beginning, or it may suddenly become so after having been, perhaps, for months or even years in a dormant condition with, it may be, little disposition either to advance or to recede. However this may be, the disease often spreads with astonishing rapidity, eating away everything within its reach—skin, connective tissue, fibrous membrane, muscle, and sometimes even bone—and often laying waste in a few days an extent of surface which it may take months, aided by the best skill, to repair. When this is the case, the action may be said to be truly phagedenic, or to consist of rapid mortification of the molecular structure of the suffering part, which is hot, œdematous, fiery red, exquisitely painful, and bathed with profuse, fetid discharges. Constitutional disturbance is great, and the tendency is usually decidedly typhoid, especially if the patient has been worn out by intemperance and other causes of depression. This form of ulcer is very prone to occur upon new and imperfectly organized skin, where it often commits the most terrible ravages, which, for a time, hardly anything can successfully resist.

Treatment.—The treatment of the acute ulcer must be strictly antiphlogistic, modified, of course, by the peculiar exigencies of the case. When the symptoms are urgent, as denoted by the severity of the local and constitutional disorder, the indication obviously is to take blood from the arm, provided the patient is at all plethoric; or, this not being permissible, at all events to open his bowels freely with an active cathartic, containing from five to ten grains of calomel, and followed up, if necessary, in six or eight hours, by infusion of senna and sulphate of magnesium. Recourse is then had to the antimonial and saline mixture to subdue vascular action; while opium is administered in large doses to allay pain and induce sleep. The diet must be mild and not too nutritious, and the patient must observe the most perfect rest in the recumbent posture. Active purgation will be found to be of the greatest value in this form of ulcer; in fact, it is difficult to imagine a case in which it could be entirely dispensed with. To render it promptly effective, however, I have long been in the habit of combining with it a certain quantity of mercury, either in the form of calomel, or blue mass, with a view of making a strong and rapid impression upon the secretions, which, as before stated, are usually notably deranged, and which thus keep up a spreading tendency in the disease. Of the beneficial effects of anodynes in arresting acute ulceration no one, who has witnessed them, can form any just conception. Their salutary impression is evidently due to the influence which they exert in tranquillizing the heart's action, and in allaying nervous irritability, which is generally so prominent a symptom in this affection; hence they should always be given in large and sustained doses from the very commencement of the malady.

It is not to be inferred from these remarks that active depletion is suited to all cases of this disease; on the contrary, we are often obliged to use tonics and stimulants at the very beginning of the treatment, and to continue their exhibition until we have succeeded in building up the system, so as to enable it to oppose a successful barrier to the encroachment of the morbid action. The state of the pulse, skin, digestive organs, and muscular system will generally serve as a correct guide to the kind of treatment best adapted to meet the exigencies of this class of cases. Quinine, iron, and milk-punch, with opium, or the salts of morphia, will usually constitute the most reliable means.

The local treatment does not differ, in its general principles, from that already described as applicable to acute inflammation, except as it respects the modifications arising from the presence of a broken surface. The part, as a primary and essential step, must be placed perfectly at rest in an easy, elevated position, to prevent arterial ingress and favor venous return; it will even be well, in many cases, to lay the limb upon an inclined plane, so that the sore shall be higher than the rest of the body, and to confine it, if necessary, in this situation by means of a light roller, applied in such a manner as not to obstruct discharge or make undue compression. If the part be filthy from want of cleanliness, or adherent dressings, ablution by immersion should precede direct medication. The use of leeches is commonly objectionable, however high the inflammation, for the reason that the bites of these animals are liable to occasion excessive pain, and sometimes even an aggravation of the disease. A much better plan is to draw blood by scarification with the lancet, the limb, firmly encircled with a cord a few inches below the knee, the while standing in a tub of warm water. From six to a dozen vertical incisions, not quite skin deep, being made over the inflamed surface around the sore, the blood is permitted to flow until the patient shows signs of approaching syncope, if he be at all plethoric, or, at all events, until the engorged vessels have been thoroughly unloaded, as denoted by the comparative pallor of the part. There is no method so well adapted as this to make a prompt and decided impression upon an acute ulcer; it is a most potent alterant, and I rarely omit its employment in any case of the slightest urgency. For the sore itself the best remedy is the officinal solution of acid nitrate of mercury, diluted with eight, ten, or fifteen parts of water, according to the foulness of the affected surface. The application should be made lightly with a soft sponge or a cloth mop, and may, if necessary, be repeated once in the twenty-four hours until there is a manifest improvement in the condition of the ulcer, when it should be entirely dispensed with, or used much weaker and more sparingly. Another valuable agent is carbolic acid; and now and then great benefit accrues from the use of chloride of zinc. As a constant covering for the parts, the most suitable one is a light emollient cataplasm, or warm water-dressing medicated with acetate of lead and laudanum, the latter being used warily, especially if the exposed surface be uncommonly large. Fetor is allayed with the chlorides. In some instances yeast may advantageously be added to the poultice. Under this treatment rapid improvement may usually be looked for; the ulceration soon assumes a more healthy character; the discharges become thicker and less profuse; the surrounding parts lose their fiery red and

œdematous aspect; and as the reparative process advances granulations spring up, and new skin forms along the margin of the old. When that point has been attained none but the mildest applications will be needed.

Such, in a few words, is an outline of the treatment which, when a choice of remedies is allowed, will generally be found to be most serviceable in this class of ulcers. But the patient will not always submit to scarification, nor is this always proper, owing to the exhausted condition of his system. Under such circumstances, the object may often be promptly attained by the free application of the dilute tincture of iodine to the parts around the sore, while the sore itself is lightly touched with the acid nitrate of mercury, as in the previous case, or with a strong solution of nitrate of silver or this article in substance, although both are decidedly inferior to the former remedy. In some instances a speedy and permanent check may be put to the ulcerative action by covering the sore and the inflamed surface with a blister, retained until thorough vesication is induced, followed by the ordinary dressings. Few cases of acute ulcers can resist this remedy. Its beneficial effects are no doubt due to the drainage which it establishes, and the consequent change in the action of the capillary vessels. The progress of the cure is sometimes embarrassed by dead matter, as shreds of connective tissue and fibrous membrane, the removal of which should receive prompt attention.

2. CHRONIC ULCERS.

While it is not always easy to determine when an ulcer becomes chronic, it is to be borne in mind, as was previously stated, that a chronic ulcer may, in consequence of local and constitutional causes, occasionally assume an acute character. In this respect the present disease does not differ from ordinary inflammation, unattended by breach of texture. Thus, an inflammation of the conjunctiva, after having pursued a chronic march, with but little pain and discoloration, perhaps suddenly, at the end of several months, breaks out with renewed vigor, characterized by all its primitive intensity, and now rapidly urging on the affected structures to permanent disorganization, rendered the more prone to this occurrence by their protracted suffering. Ulcers are not unfrequently subjected to similar hardships; not once only, but, perhaps, many times during their progress, and thus their career often becomes a most checkered one, defying alike our powers of diagnosis and treatment, and constituting at least one of the causes, previously adverted to, of the unscientific nomenclature which disfigures this branch of surgery.

When does an ulcer become chronic? or, in other words, what time must elapse before it can be said to assume this character? To this question it is impossible to give anything like a definite reply: in some instances the disease is chronic almost from the beginning; in others, it becomes so in a few weeks; and in others, again, perhaps several months intervene. The term chronic, as every one knows, has reference to time, and is employed to designate a class of affections which, having passed through their acute stages, are deprived of their primitive characteristics; their action has been modified by treatment, or by treatment and the operation of time. The inflammation now generally exists in a much milder form; there is less functional disturbance, while the constitutional derangement often entirely ceases, and the local phenomena of heat, redness, pain, and swelling are materially diminished in intensity. The part, however, is oppressed, if not overpowered, by effused fluids; its vessels are sluggish, dilated, and engorged with dark blood; nervous sensibility is perverted, and the restorative tendency is either much embarrassed or completely at a stand. Ulceration still goes on, and, perhaps, commits even serious havoc, but the action is tardy, and exhibits few, if any, of the phenomena which originally characterized it. It would seem, at first sight, as if it were a paradox to say that a disease was chronic from its commencement, and yet such is, nevertheless, the fact; rather, however, in reference to its symptoms than to the true and legitimate meaning of the term.

Chronic ulcers often exist for many months and years together; at one time stationary, now receding, now advancing; in one case exhibiting too much action, in another too little, but rarely in a condition to furnish the requisite amount and quality of reparative material. Even if granulations occasionally do form, they are seldom healthy, or, if healthy, they seldom long remain so; on the contrary, they soon languish for the want of proper support, or they perish from the violence of the attendant inflammation. These effects may be the result purely of local causes or of causes exerting their influence indirectly through the constitution; generally, perhaps, of both. If this statement be true, as multiplied observation proves, we cannot fail to deduce from it important principles of

practice. It plainly suggests the necessity, in every instance, of a careful inquiry into the nature of the exciting cause and the condition of the system, as well as the state of the part itself. To treat a chronic ulcer upon any other plan is a palpable absurdity; and yet that this is generally the case, daily experience amply attests. Few practitioners look upon this class of diseases in their true light; their ideas of their pathology are vague and indistinct; and it is, therefore, not surprising that they find themselves so often and so completely baffled in their efforts to cure them. It is for this reason that chronic ulcers of the legs have so long been regarded as an opprobrium of surgery, and that so many patients are obliged to carry their malady with them to the grave, notwithstanding the numerous attempts that may have been made to get rid of it; all arising from the fact that its true nature was never properly understood.

The chronic ulcer is capable of assuming every possible variety of seat, number, form, size, color, condition of surface, and complication. In general, it occupies the inner surface of the leg, a few inches above the ankle; but it is often situated higher up, and in rare cases it lies directly over the joint itself. The outer surface of the limb is also liable to suffer, and occasionally both sides are affected simultaneously. In fact, no part of the leg is wholly exempt from the disease, unless it be that just below the knee. The remarkable liability of the inner and lower part of the leg to the occurrence of ulcers seems to be due, in a great degree, if not wholly to the delicacy of the skin in this situation, and the very liberal supply of veins, thus rendering the tissues prone to congestion, a condition still further favored by the erect posture and by the artificial constriction of the limb, from the habitual use of the garter.

The form of the ulcer is variable, being at one time circular, now oval, and then angular, or so irregular as to defy all attempts at accuracy of description. In some cases, it extends round the limb in the form of a belt nearly of equal width. In size it ranges from a five-cent piece to that of the palm of the hand, or even the entire hand, the destruction of substance being truly frightful. In its depth, it rarely reaches beyond the subcutaneous connective tissue; in some cases, however, it involves the aponeuroses, the muscles, and even the bones and cartilages. Such ravages generally imply an unusual amount of antecedent inflammation, or the repeated intervention of acute action, although they are often produced by the steady progress of the chronic disease itself.

Although the chronic ulcer is often solitary, it is not uncommon to meet with two, three, or even a larger number, situated either in close proximity with each other, or at different, and perhaps rather remote, points of the limb. When the number is considerable, their size is usually proportionately small.

The color of the ulcer varies from light rose to deep purple, according to the intensity of the concomitant action and the congested condition of the cutaneous capillaries. The most common shades of color are the dusky, brownish, and light livid,

Fig. 21.

Chronic Ulcer with Deep Edges, partially undermined, and a Foul, Unhealthy Bottom, studded with Fungous Granulations.

but it is worthy of note that an ulcer which is of a rosy hue to-day may be of a deep purple to-morrow, simply from the change in its inflammatory condition. The parts around the sore are often as high-colored as the sore itself; sometimes, indeed, much more so. In general, the discoloration, of whatever character, is lost by insensible gradations in the surrounding healthy hue, not abruptly, as in erysipelas and erythema.

In regard to the edges of the chronic ulcer, nothing can be more diversified; hence, some of those singular distinctions of Home, Astley Cooper, and others who have followed so closely in each other's footsteps. In general, the edges are hard or callous, elevated, rather broad, and so insensible as to admit of the rudest manipulation: in some cases, they are thin, ragged, almost serrated, and either everted or inverted, and perhaps exquisitely sensitive. In another class of cases, by no means infrequent, they are considerably undermined, or shelving at one point and everted at another. In fact, there is no end to the diversities presented by the boundaries of such a sore.

The surface of the ulcer is generally more or less irregular, being deeper at one part than at another, although, as was before stated, it rarely extends beneath the subcutaneous connective tissue. Its actual condition usually varies with the amount of inflammatory action. When this is considerable, there is often an entire absence of granulations, and then the bottom of the sore will generally be found to be in a foul, bloody, or phagedenic condition, or incrusted with a stratum of lymph too feeble to admit of organization; or, finally, granulations, sloughy matter, and vitiated plasma may all be present, in varying degrees, upon different parts of the exposed surface. The concomitant discharge is profuse, sanious, fetid, and irritating, possessing none of the properties of laudable pus. The sore, as well as the surface immediately around it, is usually sensitive, and often the seat of severe pain. It is to this form of ulcer that writers usually apply the term inflamed, or irritable, from its excess of vascular and nervous activity. It is most common in nervous, irritable subjects, and in the habitually intemperate.

When the inflammation is more moderate, granulations are seldom wholly absent, and they may exist even in great abundance, although they may be altogether unhealthy. When the action is somewhat less, but not too languid, they commonly exhibit a pale, reddish, flabby appearance; their surface is irregular or tuberculated, and they are much too large; in fact, they look as if they had been reared in a hot-bed and had been too freely watered. Their reparative power is so very feeble that the surgeon is often obliged to get rid of them entirely before a cure can be effected. This state of granulation constitutes what is vulgarly called "proud flesh," and is often difficult to manage.

Again, the circulation may be inordinately languid, and then the granulations may be still larger, totally insensible, and perhaps quite œdematous, readily pitting under pressure, and, if punctured, freely exuding a serous, sanious, or ichorous fluid. Cacoplastic lymph is generally interspersed through the granulations, or adherent to the surface of the sore, the edges of which are hard and very prominent, so that the raw surface appears as if it were much below the level of the surrounding parts, which, however, it seldom is. The accompanying discharge is slight, thin, and sero-sanguinolent; while the adjoining skin is œdematous and of a dusky-brownish hue.

Finally, cases occur in which the granulations are very small, or apparently stunted in their growth, irregular in shape, of a fiery red color, and so exquisitely sensitive as to be a source of great suffering, the ulcer being intolerant of the slightest pressure, motion, or manipulation; the discharge is sanious and irritating, although seldom very fetid or profuse; the edges of the sore are thin, irregular, everted, or inverted; and the surrounding skin is actively inflamed.

The chronic ulcer is often complicated with other diseases, which tend to modify its action, and impede, if not entirely prevent, its restoration. Of these affections some are of a local, others of a general character. The former consists mainly in the involvement of the deep-seated structures, as the fibrous membranes, tendons, muscles, and bones; in the formation of sinuses; in a varicose state of the veins; and in the presence of foreign matter, under the influence of which the ulcer was, perhaps, originally induced. Eczema of the skin around the ulcer is often met with, especially in cases of long standing in elderly subjects, addicted to intemperance, overfeeding, or habitual constipation of the bowels, and is generally a source of great discomfort, if not actual suffering. The eruption usually appears in patches, studded with little vesicles, resting upon a reddish, bluish, or bronze colored base, and attended with more or less itching.

Old ulcers, especially if habitually irritated, occasionally, although rarely, become the seat of carcinomatous disease, the most common form being the epithelial. Such a change may occur in almost any part of the body, but is most frequently met with in the legs of old, dilapidated subjects.

Spots, of variable form, size, and color, often exist upon the skin in the neighborhood of chronic ulcers, and are generally an index of a degraded, depressed, or impaired action occurring most commonly on the inner side of the leg; they are of a dark purple, grayish, black, bronze, or brownish hue, are longer in the perpendicular than in the transverse direction, and are obviously dependent upon some change in the pigmentary structure of the skin. In some instances the color is pretty uniform, and involves nearly the entire circumference of the limb, forming a belt perhaps several inches in height. It is worthy of note that this pigmentary change is very often associated with a varicose condition of the veins.

Among the constitutional complications, the most common are, disorder of the secretions, especially of the liver and alimentary canal, anemia, dyspepsia, plethora, and habitual intemperance in eating and drinking. I have never seen what writers have

called the menstrual ulcer, although it is not to be doubted that great uterine derangement, showing itself in deficiency of discharge, might seriously interfere with the healing of a sore on the leg, or, indeed, on any other part of the body. An ulcer is sometimes rendered exceedingly sensitive and irritable by a gouty or rheumatic state of the system.

Treatment.—In the management of chronic ulcers the leading indications are, first, to remove any complications that may exist; secondly, to regulate the inflammatory action; and, lastly, to produce healthy granulations. If these cardinal points be kept in view, the practitioner cannot fail to settle down upon a rational and philosophical plan of treatment, destined to be crowned with success. It is only necessary to treat the disease as one of ordinary inflammation, modified by accidental circumstances. The great object in every case is to bring the ulcer into a simple granulating condition, so as to afford nature an opportunity of beginning and carrying on the healing process without impediment.

Ulcers sometimes refuse to heal in consequence of the partial destruction of aponeurotic, tendinous, or muscular tissue, or the manner in which the parts are compressed by overlying structures; in the former case, the dead substance is removed with the knife or scissors; in the latter, relief is afforded by adequate incisions, after which the malady is treated upon general principles. Necrosed bone is extracted with the forceps, while carious bone is scraped away, or removed with the chisel, gouge, saw, or scalpel.

Varicose veins are dealt with according to the rules laid down for the management of that disease in a subsequent chapter: the complication is often a serious one, and nothing short of the ligation of the affected vessels, or their destruction with Vienna paste, answers the purpose. When the malady is comparatively slight, amelioration may be afforded by wearing an elastic stocking to give uniform support to the limb, and by the free use of spirituous lotions, with the occasional application along the track of the enlarged vessels of dilute tincture of iodine. Hemorrhage sometimes attends this complication, from extension of the ulceration into a contiguous vein: I have seen cases where more than a quart of blood was thus lost in a few minutes, and I am cognizant of two instances in which the bleeding was so copious as to prove fatal. The proper remedy is compression, followed, if need be, by a Vienna paste issue to produce permanent obliteration of the vessel at the seat of the ulceration.

Sinuses are laid open with the director and bistoury, their course being completely traced out, as no cure is to be expected so long as any portion remains concealed. Reunion of the incision is opposed by the tent and by careful dressing.

Ulcers, consequent upon wounds, are frequently prevented from closing by the presence of foreign matter, as a pellet of paper, a piece of cloth, a ball, nail, or fragment of bone. In such an event, a careful search is made with the probe, and the substance, if detected, is extracted in the usual manner.

In an ulcer attended with undermined, inverted, ragged, or very callous edges, the proper plan is to use the knife, cutting off all that is spoiled, redundant, or irreclaimable. Exuberant granulations are similarly dealt with, excision here being far preferable to escharotics, the action of which is always painful, tedious, and uncertain.

Ulcers complicated with hemorrhage are treated upon general principles. The blood may proceed from an artery or vein, laid open by the morbid action, or it may ooze from numerous points, as when there is a dissolved state of the blood, or a hemorrhagic diathesis. In what English surgeons call the menstrual ulcer, the discharge is generally vicarious of, and consequently coincident with, the menstrual flux, and usually readily disappears under tonic treatment, as iron and quinine, with exercise in the open air, saltbathing, and other invigorating measures.

The second object is to reduce the concomitant inflammation, in order to enable the sore to form healthy granulations, which it cannot do so long as the morbid action is either very high or very low. One step towards accomplishing this end is the removal of complications, which, indeed, is frequently of itself sufficient to effect a cure. When this fails, the rest of the inflammation is often readily relieved by the application of dilute tincture of iodine to the parts immediately around the ulcer, preceded, when the congestion and discoloration are unusually great, by free scarification; and by touching the sore itself very gently, once a day, with solid nitrate of silver, or, what is better, the officinal solution of acid nitrate of mercury, variously weakened, according to the exigencies of the case. One such application in the twenty-four hours usually suffices, and in many instances the cure will progress more rapidly and satisfactorily if it be made less frequently. Other topical remedies may often be advantageously used, especially the nitric acid lotion, and solutions of acetate of lead and opium. As a constant protection for the parts, nothing is more suitable than an elm or a linseed cataplasm, which, notwithstanding

the abuse that has been heaped upon it, is still, in most cases, one of the neatest and most trustworthy remedies. Or, instead of a poultice, warm water-dressing may be used, medicated, when the pain is very great, with solutions of morphia, or morphia may be cautiously sprinkled directly upon the surface of the ulcer.

When the healing process is impeded by the indurated, disorganized, and contracted condition of the tissues immediately around the ulcer, there is no method of treatment so likely to be beneficial as the one originally suggested by Mr. John Gay, of London, consisting in the thorough division of the parts by drawing the knife elliptically through the skin, connective tissue, and aponeurosis a short distance from the sore, thus severing their adhesions, and changing their action; in other words, placing them under entirely new relations. The operation is often quite bloody, especially when it involves, as it occasionally does, large veins; but the flow, which is usually productive of great benefit by relieving the engorged vessels, is always easily controlled by means of styptics and compression.

Whatever local measures be adopted, strict attention must be paid to the state of the system; the bowels must occasionally be relieved with mild aperients, and care must be taken that the diet is perfectly mild and not too nutritious. If the general health is much disordered, recourse is had to more active purgation, and to the free use of antimonial and saline medicines, with a full opiate at night, especially if there be much pain, or inability to sleep. Bleeding at the arm will be required only in very plethoric subjects, in urgent cases. When an ulcer is associated with a gouty or rheumatic state of the system, the use of colchicum, salicylic acid, and other suitable remedies is indicated. Absolute recumbency is observed, at least until the morbid action has been measurably subdued; and the affected part is placed at rest in an easy, elevated position, precisely as in ordinary inflammation.

If the general health is much reduced by protracted suffering, or if the system is in an anemic condition, or, finally, if typhoid symptoms are present, stimulants and tonics will be indicated, especially quinine and iron, with milk-punch, nutritious food, and change of air.

If the measures now detailed be judiciously employed, the ulcer will soon be placed in a suitable condition for the development of healthy granulations, fig. 22, after which little else will be necessary than to watch the parts, with a view to the prevention of overaction.

Fig. 22.
Granulating Ulcer, beginning to Cicatrize; the Process extending from the Periphery towards the Centre.

The mildest and most soothing applications will now generally suffice, the object being rather to protect the surface of the sore from the injurious contact of the atmosphere than to promote its welfare by direct medication. Among the best of these remedies are ointments prepared with opium, acetate of lead, balsam of Peru, oxide of zinc, and above all, the ointment of the acid nitrate of mercury, diluted with ten to twelve times its weight of cosmoline. Its cicatrizing properties are far greater than those of any other substance I am acquainted with. When the ulcer is very sensitive or irritable, iodoform or chloral may be used, either in a solution or in the form of unguent. Iodoform rendered odorless by admixture with oil of aniseed is sometimes highly serviceable in the treatment of the more obstinate form of old ulcers. It should be applied in a thick layer, the sore being previously well cleansed and dried, and afterwards carefully strapped with soap and mercurial plaster, daily renewed. Any disorganized matter should be thoroughly scraped away, as a preliminary step, to promote the development of healthy granulations. The scabbing process may often be expedited by touching the granulations very lightly, once a day, along the edge of the sore, for the space of a line, with solid nitrate of silver.

Rest in the treatment of ulcers is indispensable to a rapid cure, and yet instances constantly occur where, either on account of the patient's condition in life, or the exhausted state of his health, exercise in the open air is absolutely necessary; under these

circumstances, the part should be as carefully protected as the exigencies of the case will permit, fatigue and protracted dependency being especially guarded against. The bandage in particular will usually be found to be a powerful adjuvant both to comfort and cure ; but it must be applied equably from the distal portion of the limb upwards, and not in folds or creases, otherwise it will do infinite harm. It must be changed at least once a day, being replaced as soon as the limb has been thoroughly cleansed and the sore properly dressed. In hot weather, it may occasionally be kept constantly wet, with good effect, with cold water, spirituous lotions, or weak solutions of lead and opium. In winter the " domette " flannel bandage is preferable to the ordinary roller, as it is both warmer and more elastic.

A most important step was made a few years ago, in the treatment of chronic ulcers by the use of the elastic bandage, originally recommended by Dr. Henry A. Martin, of Boston. It is particularly applicable to the treatment of old ulcers attended with varicose enlargement of the veins, or an eczematous condition of the skin, and is far superior to the treatment by the ordinary roller and Baynton's dressing, so long in vogue in such cases in this and other countries. The plan consists in enveloping the affected limb in what is known as the solid rubber bandage, applied spirally from near the toes upwards in such a manner as to afford firm and equable support to the parts. The bandage, which should be about two inches and a quarter in width by ten to twelve feet in length, and furnished at the upper end with two tapes for fastening, is removed every night, washed, and reapplied in the morning, the sore and the surrounding surface having been previously well cleansed with soap and water. No protective is placed upon the ulcer, unless, as occasionally happens, the bandage acts for a while as an irritant, when the interposition of a piece of gauze or of thin patent lint may become necessary. The bandage during the first few days is generally productive of some inconvenience, caused by the increased heat and the confinement of the secretions ; but this soon subsides, and is followed by so much relief that the patient would be unwilling to go without it even for a day. In some cases, especially in persons of delicate skin, a few vesicles or even pustules are liable to form, and the epidermis is apt to become so much softened and macerated as to give rise to disagreeable feelings. The same bandage can often be worn for months, and even years, and is therefore a great desideratum with poor patients, who are thus enabled to perform their daily labor with entire comfort. If, at any time, the sore becomes inflamed, it may be covered with a poultice at night. The bandage should always, if possible, be reapplied before the patient leaves his bed, and, consequently, before the veins become distended with blood.

The method of Baynton sometimes furnishes very good results, especially in small ulcers attended with great thickening and induration of the skin. It consists in strapping the sore and adjacent parts with adhesive plaster cut into strips, varing from an inch to an inch and a quarter in width, and long enough to extend about three-fourths around the limb, each one being so arranged as to overlap that which is below it, and drawn so firmly as to afford uniform support to the affected surface, as in fig. 23. The dressing, which is completed by enveloping the limb in a bandage from the toes as high up as the knee, should not be changed, on an average, oftener than twice a week. Occasionally, as when the ulcer is associated with a varicose state of the veins of the extremity, the entire foot and leg may be beneficially enveloped with adhesive plaster for some distance above the sore, as originally suggested by Mr. Critchett. In my own practice I have often found that the mere covering of old, granulating ulcers with adhesive plaster, by protecting them from the air and the friction of the clothing, is highly favorable to their cicatrization.

Fig. 23.

Mode of Strapping of an Indolent Ulcer.

In cases of long standing, the surface of the ulcer may sometimes be advantageously protected with an artificial crust, consisting of an ointment composed of three parts of prepared chalk and two of fresh lard, the former being previously reduced to a very fine

powder, and then gradually stirred into the latter, melted in a vessel over a slow fire. The ointment is applied once a day upon a piece of lint, and the limb is supported either with Baynton's dressing, or a flannel bandage, as suggested by Mr. J. K. Spender, the author of this mode of treatment.

A powerful impression may generally be made upon an atonic or indolent ulcer even in a few days by the use of galvanism. The current is transmitted through a copper wire from six to eight inches in length to a thin silver plate, of suitable size and shape, applied to the sore, and connected with a small zinc plate placed upon the sound skin a short distance off, a piece of chamois leather, soft sponge, or paper lint, moistened with vinegar, intervening. The apparatus is held in position by a bandage or by adhesive strips. Under the stimulus thus produced, healthy granulations are rapidly developed, with a strong tendency to cicatrization.

There is great art in dressing an ulcer. Everything like rude manipulation and protracted exposure must be avoided; the sore is never wiped, or even touched with the finger, and, while the necessary ablutions are going on, the limb is carefully supported over a basin or small tub, the water, which may be either cold or tepid, being gently squeezed upon it from a sponge held at a distance of several inches. The secretions being thus disposed of, the surrounding surface is properly dried, and the dressing reapplied. If fetor be present, a little permanganate of potassium, chlorinated sodium, or carbolic acid is mixed with the water employed in cleansing the sore, as well as sprinkled from time to time upon the poultice and bandage. When the discharge is unusally abundant, oakum may be advantageously used to absorb the matter. The eczema so liable to complicate old ulcers of the leg is generally promptly relieved by a brisk laxative, a cooling diet, and the application of benzoated zinc ointment, or dilute ointment of acid nitrate of mercury. If much inflammation be present, a weak solution of actetate of lead will be the most suitable remedy.

The cicatrization of ulcers, as will be shown in another chapter, is often greatly promoted by skin-grafting, or by the insertion of little bits of integument into different parts of the affected surface. To insure the success of the operation, it is essential that the sore, as well as the adjacent skin, should be as free as possible from inflammation, that the granulations should be of a healthy, florid complexion, and that the discharge should possess all the properties of what is called laudable pus. When these characteristics are present, it is an evidence that both the part and the system are in a good, sound condition, and that skin-grafting may be performed with every prospect of expediting the healing of the sore by establishing more or less numerous centres for the formation of a new skin.

Whatever mode of treatment be employed, it is essential, as it respects the prevention of relapse, that the patient should observe great care in regard to his exercise and diet, for a number of weeks after the ulcer has completely healed. If he indulges his appetite too soon, neglects his bowels, or allows his secretions to become disordered, he can hardly escape a new outbreak of the disease, especially if, at the same time, he fatigues his leg much, lets it hang down constantly, constricts it improperly with his garter, rubs it with his boot, or permits it to become covered with filth. Cleanliness, indeed, cannot be too rigidly enforced as a means of promoting healthy action. The parts should be thoroughly washed at least once a day with soap and water, and then sponged with some alcoholic lotion, to revive and invigorate their exhausted powers.

In inveterate cases, extensively involving the osseous tissue, greatly impairing the general health, and resisting the best efforts of the surgeon for their relief, the only resource is amputation, performed through a sound portion of the limb. Such a procedure, however, will, I am sure, be rarely demanded in these days of conservative surgery; for, unless the bone is almost entirely destroyed, it will be easy, in the majority of instances, to dispose of the diseased structures with the knife, gouge, and mallet, or by resection.

Finally, the question may be asked, is it always safe and proper to heal old ulcers? Upon this subject, various opinions have been expressed by writers on surgery. Those who assert that it is not, assume that such sores act as issues, which serve as safety-valves to the system, by ridding it of redundant, if not positively peccant, humors. They allege that cerebral apoplexy and other serious diseases have occasionally occurred as the direct and speedy consequences of the drying up of old ulcers. Those, on the contrary, who espouse the opposite side of the question, declare that such attacks are mere accidental circumstances, readily explicable by the laws of coincidence; a view which I have myself always adopted. It is questionable, indeed, whether surgical science possesses any well-authenticated facts by which this opinion can be sustained. I have often cured ulcers of five, ten, and even fifteen years' standing, constantly attended with more or less discharge and

irritation, and yet no instance to which such an event could justly be ascribed has ever fallen under my notice. Besides, the constitutional treatment that is usually necessary in these cases to effect relief, is, in itself, almost a guarantee against attacks of grave disease in other parts of the body. If, however, such an occurrence should be dreaded, it would be easy, while the sore is drying up, to protect the system by a continuance of the constitutional remedies, especially a spare diet, and the occasional use of a purgative, conjoined with the employment of an issue in a remote region of the body, as the arm, chest, or neck.

SEC. X.—GRANULATION.

Granulation is the means by which lost tissues are replaced and wounds healed when they fail to unite by the first intention, or by adhesive action. The process is one of great interest, whether it be viewed merely as a physiological phenomenon, or as an operation employed by the system to restore injured and mutilated structures. An intimate knowledge of its nature and habits is, therefore, of great importance to the surgeon.

It is chiefly upon the external surface of the body that an opportunity is afforded of examining this process with any degree of satisfaction. In the various mucous outlets it is more difficult to watch and to trace it through its different stages; while in the internal organs it either does not occur at all, or is observable only after death.

It may be assumed, as a law, that high vascular excitement and repair are incompatible with each other. Hence, before the process in question can fairly begin, there must be a material abatement of the inflammation. As soon as the balance of action has thus been reëstablished, the breach is covered with red, fleshy-looking bodies, technically denominated granulations. By a continuance of this action the developmental process steadily progresses until the gap is finally filled up and scabbed over.

A granulation is a highly organized body, capable of executing highly important functions. It consists essentially of capillary vessels, the interstices of which are occupied by small, soft, round, nucleated, embryonic cells, heaped upon each other without any particular order, and connected together by a minute quantity of amorphous, mucous intercellular substance. It is usually of a florid color, very vascular, extremely sensitive, and of a conical, rounded, or oval shape, its volume varying from a mustard-seed to that of a large shot. Its vessels, which are remarkably numerous, are evidently, for the most part, outgrowths of those of the adjacent parts, and are arranged, as seen in fig. 24, from Billroth, in the form of beautiful loops and arches, closely interwoven with each other. As they are developed with great rapidity, their walls are at first so extremely delicate as to yield to the slightest pressure; hence there is generally more or less hemorrhage whenever anything is rudely brought in contact with them. The veins are very large, tortuous, and convoluted.

Fig. 24.

Bloodvessels in Granulations.

Although no nerves are demonstrable in granulations, they are unquestionably abundantly supplied with them, as is shown by the fact that they are often very sensitive, especially when diseased. The existence of lymphatic vessels also is a matter of inference rather than of positive proof. Observation shows that certain articles, placed in contact with a granulating ulcer, are promptly taken up, and carried into the system, producing a similar effect, nearly in as short a time, as when introduced in the ordinary manner. Thus, morphia readily allays pain and induces sleep; atropia dilates the pupil; arsenic irritates and inflames the stomach; strychnia convulses the muscles. Moreover, a granulation is a secreting body, a kind of compound gland, capable of pouring out plasma and providing the elements of pus; the former for enlarging its own dimensions and multiplying itself; the latter as a means of defence from the atmosphere and the surgeon's dressings.

Granulations form with various degrees of facility, depending mainly upon the nature of the part and the amount of inflammatory action. Ulcers of the skin and connective tissue always, other things being equal, furnish them most readily, as well as in greatest abundance; a circumstance evidently due to their extreme vascularity and high nervous endowment. Bone, cartilage, tendon, and fibrous membrane, on the contrary, granulate more slowly, and hence injuries of these structures are always repaired with more difficulty. The same rank applies, only more pointedly, to scirrhous and other malignant ulcers.

The bodies are sometimes developed subcutaneously. Paget states that he has seen a mass of florid granulations in a case of simple fracture, in which the ends of the bones had remained long ununited, and a similar phenomenon is occasionally witnessed in Pott's disease of the spine. In a case of caries of the ribs and costal cartilages in a young man, I found the bottom of the ulcer studded with numerous fine, florid granulations, although the opening in the skin, hardly the size of a common probe, was nearly three inches distant; and in a case of hematoma of the burse of the patella in a young woman, a patient at the College clinic, I found, after the semiorganized clots were scraped away, numerous well-formed bodies of a similar kind upon the walls of the cyst, the overlying integument being perfectly healthy.

In examining a cluster of granulations, a great difference may generally be observed in their character. The deep-seated ones are comparatively firm, more or less elongated, and of a fibroplastic structure, if not actually filamentous. The superficial, on the contrary, are in a rudimentary state, very soft, lacerable, and extremely vascular. At the edges of the surface, near the junction of the new and the old tissues, they possess the properties of incipient epithelial cells.

Granulations are liable to disease. This often occurs from causes apparently the most insignificant; depending, perhaps, at one time upon the state of the part, at another upon the state of the constitution, or upon both combined, but more frequently upon the nature of the dressing, and the indiscretion of the patient. Hence, the appearance of these bodies usually serves as an index of the concomitant action, local and general, and affords useful indications of treatment. The most important alterations which they undergo are such as relate to their size, color, consistence, and sensibility. Healthy granulations are generally small, not exceeding the volume of a mustard seed, but cases occur in which they are many times larger. Their natural color is a beautiful florid; when congested or inflamed they assume a purple, livid, or brownish aspect, while under opposite states they are occasionally pale, or even blanched. In their consistence these bodies may, on the one hand, be very soft and lacerable, and, on the other, very firm, inelastic, and almost callous. Occasionally they have an infiltrated, œdematous, or dropsical appearance, serum escaping freely upon the slightest puncture. Their sensibility is usually very feeble, except in very nervous, irritable persons, in whom they are sometimes exquisitely painful, particularly if they are much inflamed. In ulcers from burns the granulations are always distinguished by their excessive tenderness and by the rapidity of their growth.

The discharge furnished by these bodies varies very greatly. When they are in a perfectly normal condition, as indicated by their florid aspect, small size, and steady development, it is usually of a thick, cream-like consistence, and of a pale yellowish color, or, in other words, of the nature of laudable pus; if, on the other hand, they are inflamed and irritable, it will generally be thin and sanious, with an inordinate quantity of earthy salts; when the excitement is very high, the matter is usually mixed with aplastic lymph; hard, callous granulations are often free from all discharge, being apparently incapable of furnishing any matter whatever. In dropsical granulations the fluid is usually serous.

The management of the granulating process must be conducted upon the same general principles as the ulcerative. The leading indication is to favor its development by protecting the raw surface from the atmosphere and whatever else has a tendency to embarrass its progress. The most suitable applications, as a general rule, are water-dressings and emollient poultices, employed in such a manner as, on the one hand, not to excite exuberant action by their warmth, and, on the other, not to repress growth by their refrigerant effect. Rude contact, protracted exposure to the air, and irritating applications must be carefully avoided.

SECT. XI.—CICATRIZATION.

Cicatrization is the completion of the granulating process, the last act in the operation of repair, the hermetic sealing, as it were, of the breach left by the destruction of the tissues of the affected part.

Cicatrization must always necessarily be preceded by a subsidence of the inflammation of the part, just as is the development of granulations, only to a still greater extent. This is an essential preliminary. The granulations having attained the level of the skin, their growth is arrested, and their vessels coalesce so as to form a continuous gelatinous tissue. The next step is a deposit of plasma at the edges of the breach, followed by its rapid organization and conversion into a thin, bluish, or whitish pellicle, abounding in epithelial

scales, and strikingly contrasting, by its peculiar appearance, with the granulations and the adjoining skin. The new substance is always easily detached with the sponge or finger, for as yet its consistence is very slight. Gradually, however, it becomes more thick and firm, assimilating itself more and more closely to the preëxisting integument, whose place it is intended to supply. The process, thus begun, continuing, the plastic, organizable film extends steadily onward until the exposed surface is finally completely covered in, the length of time necessary for this varying according to the size and shape of the breach, the absence or presence of complications, and the state of the system. The majority of the cells of the granulation tissue now disappear by disintegration and absorption, and the gelatinous intercellular substance is converted into fibrillar connective tissue, while the remaining cells assume the characters of connective tissue corpuscles. The superfluous capillaries become obliterated, and the new tissue contracts more and more, until a perfect cicatrice is formed. Ovoidal ulcers or wounds heal, other things being equal, more rapidly than circular, superficial than deep, common than specific. Cicatrization is usually more easily accomplished in the upper extremities than in the inferior, and in the skin and connective tissue than in the other structures. In the organs, properly so called, it generally takes place with difficulty, and only after a long interval.

Cicatrization, as a general principle, always begins at the edges of the breach which it is designed to repair, whence it proceeds towards the centre, which is, consequently, the last to heal. So constant and uniform is this occurrence, that it may be regarded as the great law of cicatrization. It would seem as if the aid of the natural tissues were necessary to enable the new substance to obtain a secure foothold. If, occasionally, an example of an opposite character presents itself, it is simply exceptional, and it cannot, even then, always be determined whether the starting point of the process was not a small fragment of the old structures, which, standing like a little island in the midst of the ulcer, serves as a nucleus to the new. Obviously, in such an event, there is no new law in operation.

Some time necessarily elapses, after the cicatrization is completed, before the new structure, now called a *cicatrice*, acquires much solidity and strength. It is only by degrees that it loses its bluish appearance and assumes the properties of the preëxisting substance. Even then it is at best only a very imperfect copy of the original, whose place it is designed to supply, being destitute alike of hair, sebaceous follicles, and sweat glands. Its vessels, at first remarkably large and tortuous, gradually dwindle down to the size of the natural ones, in the adjacent sound parts, and, when fully developed, generally exhibit a beautiful retiform arrangement, as in fig. 25. The scar always remains tender for some time after its formation, is very liable to break, crack, or ulcerate from the slightest causes, and has a **remarkable tendency to contract or diminish.**

Fig. 25.

Structure of a Cicatrice of the Skin.

What is true of the imperfect reproduction of the skin is equally true of all the textures with the exception of the nerves and muscles in which perfect regeneration both as regards form and function occurs. Of the other tissues new bone comes, perhaps, nearer to the original structure than any other; but even this presents many peculiarities, and it is certain that it often acquires a degree of hardness and solidity far greater than that of the primitive substance. There are, moreover, some pieces of the skeleton which, when broken, unite, not by osseous matter, but by fibrous tissue, fibro-cartilage, or cartilage. Fractures of the patella, the olecranon process, the acromion process of the scapula, and the neck of the thigh-bone within the capsular ligament, are generally, if not invariably, repaired after this fashion, because the ends of the fragments, deprived of their natural supply of blood and nerve-fluid, are unable to pour out the requisite quantity of phosphate and carbonate of lime, to insure their solidification. Cartilage is imperfectly reproduced after injuries; the new substitute is always very thin, hard, and of an unnaturally bluish tint. In fracture of the costal cartilages the consolidation is effected by bone. Tendon is renewed only in the case of subcutaneous section; never when lost by disease. Bloodvessels are never regenerated; their continuity cannot be reëstablished after complete division, on account of the retraction of their extremities. The cerebral, pulmonary, hepatic, splenic, salivary, renal, and seminiferous structures are incapable of reproduction, the new substitute being always of a cellulo-fibrous, fibrous, or fibro-cartilaginous nature. Serous, mucous, and fibrous membranes are repaired in a similar manner. Thus, it will be seen that a tissue, when seriously mutilated, is seldom perfectly reproduced, whatever pains may be taken to assist its efforts.

It is not surprising that a substance so imperfectly organized as a cicatrice should be liable to inflammation and its consequences, as well as to some of the new formations.
Its powers of resistance being naturally feeble, it generally yields more readily to disease, whether simple or malignant, than the original structures. It is for this reason that inflammation of the substitute-tissue is prone to pass into ulceration, or if the morbid action is at all severe, even into mortification. In suppuration, the matter furnished by the part is nearly always of a thin, ichorous nature, a development of genuine pus being almost impossible under any circumstances.

When a cicatrice is habitually exposed to pressure, it has a great tendency to change into a species of corn, not unlike a corn upon a toe, both in color, shape, and consistence. In other cases, again, it may be transformed into a bunion, burse, or synovial cyst, as upon the extremity of an old stump, especially after amputation of the thigh and leg. A genuine horny growth sometimes occurs upon a cicatrice ; and occasionally the new tissue, from the effects of long-continued pressure, undergoes the cartilaginous, fibro-cartilaginous, or even the osseous degeneration.

A true neuroma is sometimes developed in such a structure, as in a case recently under my charge, in a man, thirty-five years of age, who, twelve months previously, received a lacerated wound in the left middle finger. The parts were long in healing ; and at length an exceedingly hard, ugly scar formed, exquisitely sensitive on the slightest touch, considerably elevated above the surrounding level, and habitually of a red-purplish hue. The tenderness was always worse in cold, damp states of the atmosphere, and, under such circumstances, the pain not unfrequently extended along the forepart of the arm, as high up as the elbow. The principal mass of the growth consisted of an expansion of the digital nerves, incased by dense, fibroid tissue.

The most common form of malignant disease to which cicatricial tissue is liable is epithelial carcinoma ; it may occur upon any part of the body, but is most frequently met with upon the face, hands, and feet, parts which are habitually exposed, or constantly subjected to pressure and friction. The diseased structure, almost of stone-like hardness, and the seat of sharp, pricking, or burning pains, soon ulcerates, and pours out a thin, sanious, and fetid fluid, highly irritating to the neighboring healthy surface. The edges of the sore are hard, steep, everted, or partially undermined, while the bottom is foul and slightly covered with spoiled lymph : occasionally the part has a worm-eaten appearance. The ulcer is always intractable, and, steadily proceeding from bad to worse, is eventually followed by the most serious consequences.

Keloid is another form of disease liable to appear in cicatrices ; this, as will be seen elsewhere, is a peculiar fibroplastic growth, which often forms after burns and scalds, and which derives its name from the supposed resemblance which it bears, in its configuration, to the claws of a crab.

There are certain cicatrices which are habitually dry, painful, and the seat of more or less itching, with a tendency to ulceration and discharge. Old stumps of the leg and thigh, imperfectly covered with integument, with the raw substance firmly adhering to the ends of the bones, are very apt to suffer in this way, and to be a source of perpetual annoyance. Not unfrequently the pain is of a neuralgic character, especially when it is dependent upon the presence of a neuroma, or a bulbous expansion of the nerves. Lastly, the pain, of whatever nature, is often materially influenced and aggravated by hygrometric conditions of the atmosphere, the part and system being conscious of the slightest change of the weather.

Finally, cicatricial tissue sometimes manifests a remarkable disposition to contract, even long after it has apparently attained its full development. This tendency is nowhere more conspicuous than in burns and scalds, where it is occasionally so great as to give rise to the most hideous deformity. Thus, a vicious scar may pinion the arms to the side, retract the hand upon the wrist, and pull down the chin upon the chest. The new tissue, consequent upon the loss of substance caused by salivation, generally contracts in such a manner as to produce firm adhesion of the jaw, sadly interfering with eating, mastication, and even articulation.

In order to prevent the degeneration of a cicatrice, especially if large, it should be protected for a long time from rude manipulation, pressure, friction, and irritating applications. Any tendency to undue contraction should promptly be counteracted, otherwise it may lead to great deformity and impairment of function. A vicious cicatrice may occasionally be advantageously extirpated.

CHAPTER V.

TEXTURAL CHANGES.

UNDER this head may be described those organic changes which are effected in the substance of the organs and tissues, as the result either of inflammation or of defective nutrition, consequent upon lesions in the circulatory and nervous systems. The most important of these alterations of texture are softening, induration, transformations, hypertrophy, atrophy, contraction, and fistule.

SECT. I.—SOFTENING.

Inflammation not unfrequently passes into softening, or what the French pathologists have denominated ramollissement. The event is characterized by a loss of cohesion of the affected textures, varying in degree from the slightest change of the natural consistence to almost complete pulpifaction. All parts of the body are liable to this occurrence, but those which are most apt to suffer are the lungs, brain, spleen, liver, and heart, together with the mucous membrane of the stomach and bowels, the articular cartilages, and the spongy structure of the bones. The subcutaneous and intermuscular connective tissue is occasionally softened to a great extent in rapidly progressive forms of inflammation, particularly in diffuse erysipelas. On the other hand, the vessels, nerves, muscles, and tendons, the fibrous and serous membranes, the lymphatic and salivary glands, the kidneys, the thyroid body, uterus, ovaries, testes, and prostate rarely experience this alteration, however violent the attendant action.

Softening sometimes occurs rapidly, at other times slowly; hence the distinction into acute and chronic. In the former case the affected tissues may be almost completely deprived of their natural consistence within the space of a very few days. Thus, in acute pneumonia the lungs are often so much softened at the end of this time as to be incapable of resisting the slightest pressure of the finger. In the brain and spleen the loss of cohesion sometimes proceeds even more rapidly than in the lungs. Chronic softening is most common in the cerebral substance and in the mucous membrane of the ileum and colon, where it is generally a most insidious disease, often involving a large extent of tissue, and yet unaccompanied by any characteristic symptoms.

The true nature of softening has not been explained. We can, however, hardly divest ourselves of the idea that it is a species of molecular mortification, especially in its more advanced stages. Be this as it may, it is unquestionable that the loss of cohesion, under such circumstances, is entirely incompatible with the exercise of the functions of the part, or its restoration to health. Many of its smaller vessels are completely obliterated, while the remainder are so crippled and paralyzed as to be scarcely able to propel their contents. Changes not less conspicuous are observable in the proper parenchymatous structure, which not only loses its natural consistence, but also its natural color; its cells are infiltrated with serosity, or serosity, lymph, pus, and blood, and its minute texture is no longer distinguishable by the aid of the most powerful microscope. If this is not death, or a condition closely approximating to it, what is it? In the milder forms of mollescence the structure may still retain some vitality, and may, consequently, be able, in time, to regain its original characters; or, what is more probable, may be rebuilt by plastic matter, after the manner of other broken-down and mutilated tissues, the first step in the process being the removal of the effete substance.

There is a species of softening which is intimately connected with, if not actually dependent upon, obliteration of the vessels of the affected structures, with consequent deficiency of blood and impairment of nutrition. It is most frequently met with in the brain and spinal cord of old persons, and is generally supposed, although perhaps erroneously, to be of a non-inflammatory character. If this opinion were correct, it is not probable that we should find, as we always do in this disease, more or less effusion of serum, plasma, and even pus. Wherever these fluids are deposited, they afford indubitable evidence of incited

action; and it would, therefore, be absurd to conclude that they could be poured out here without the agency of inflammation.

This event of inflammation is interesting chiefly in a pathological point of view; for, as it is met with almost exclusively in the internal organs, and presents no characteristic symptoms, it is evident that treatment holds out little prospect of relief. When the true nature of the lesion is suspected, the proper remedies, in the acute form, will be such as are calculated to reduce inflammatory action and to favor the removal of deposits; in the chronic variety a mildly alterative course, with tonics, embracing cod-liver oil, quinine, and iron, is indicated.

SECT. II.—INDURATION.

A deposit of lymph, plasma, or fibrin is common to nearly all inflammations, whatever may be their cause, site, or degree. When occurring upon the free surfaces of the organs, it usually presents itself in the form of a layer, which, escaping the influence of the absorbents, is ultimately converted into an analogous tissue, which often remains during the rest of the individual's life, subject, in the meanwhile, to all the diseases and accidents incident to preëxisting structures. When the deposit takes place in the substance of the organs, it fills up their cells, interstices, or molecular spaces, and thus increases their consistence, as well as their weight, the matter assuming the shape of the cavities in which it is lodged, and being liable, as in the former case, either to be absorbed or to become organized, according to the condition of the part and the vitality of the morbid product. A similar arrangement occurs when plasma is effused into the connective tissue beneath the skin, among the muscles, and in other situations.

Induration is extremely common, and may occur in any organ and tissue of the body. It is most frequently met with, however, in the lungs, spleen, liver, thyroid gland, testicle, lymphatic and prostate glands, mamma, ovaries, uterus, bones, and subcutaneous connective tissue.

Age exerts considerable influence upon the production of induration. In the great majority of the organs it may occur at any period of life, but in some, as in the thyroid gland, for example, it rarely appears before the fourteenth year, while in the genital apparatus it is hardly even observed until after puberty. Induration of the prostate gland, of the vessels, and of the brain and spinal cord is an affection of advanced life, as is also induration of the crystalline lens and its capsule.

The degree of induration varies from the slightest alteration of the natural consistence of the part to the solidity and density of concrete albumen, old cheese, fibro-cartilage, cartilage, or bone. Much, in this respect, will depend upon the nature of the affected tissue, and the date of the lesion, or the degree of change which the deposit upon which the induration depends may have undergone. The color of the affected part may be normal, or variously altered, according to the amount of its vascularity and the presence or absence of effused blood. Much diversity also exists in regard to its volume, although in most cases this is considerably augmented, and sometimes even quite enormously, the bulk many times exceeding that which is natural to the organ in health. The weight of the part, too, is usually increased, and there is commonly some dryness, with a marked loss of elasticity.

The period required for the production of induration ranges from a few hours to several days, weeks, or months, depending upon the nature of the exciting cause and of the affected structures. In the testicle it often occurs in a very marked degree in less than twenty-four hours, and at the end of forty-eight hours the organ may be so hard as to be entirely incompressible. The induration accompanying the development of tonsillitis, adenitis, furuncle, carbuncle, and erysipelas generally occurs with extraordinary rapidity, and the same thing is frequently witnessed in the connective tissue around the joints, especially in inflammation of a gouty or rheumatic character. In pneumonia the parenchymatous substance of the lungs is often extensively solidified within a few days from the commencement of the morbid action. On the other hand, the induration may proceed very slowly, as in goitre, chronic arteritis, hepatitis, and splenitis, and in certain affections of the uterus and prostate gland, where months, if not years, may elapse before it attains its full development.

The effect of induration upon the tissues in which it occurs is of the most prejudicial character, sadly impairing their structure and functions and frequently leading to the worst results. Thus, when it exists in both testicles it may become a cause of impotence; in the liver it may interfere with the secretion of bile; and in the lung it may produce death by offering a mechanical obstruction to the ingress of the air. In the arteries in-

duration is frequently followed by rupture of their coats, leading to aneurism; while in the connective tissue around the joints it always impedes the exercise of the articular surfaces.

The immediate cause of induration is a deposit of plastic matter in the cells of the affected structures, which it thus obliterates while it condenses the adjoining substance, and so renders it unfit, either temporarily or permanently, for the proper exercise of its functions. The fluid is generally associated with more or less serum, and not unfrequently also with pus and even pure blood. When the circumstances under which it is deposited are favorable, it soon becomes organized, and may finally be converted into an analogous tissue, which often retains its parasitic connection during the remainder of life, although in most cases it ultimately disappears.

In the treatment of induration the leading object is to excite the absorbent vessels so as to induce them to remove the deposits upon the presence of which the lesion depends. The sooner this is always done the better. The longer we wait, the greater will be the danger of a permanent change of structure, or, when the organ is one of great importance to life, of the death of the patient. When the deposit is recent, and action still high, our reliance is mainly upon the vigorous employment of antiphlogistics, as bleeding, purging, and diaphoretics, with antimonials, light diet, and rest in the recumbent posture. Inflammation having thus been moderated, the induration, already greatly reduced by the previous measures, may usually be promptly disposed of by alterative doses of mercury, carried, perhaps, to slight ptyalism; and, when the part is accessible, by sorbefacient liniments, embrocations, and unguents, aided by pressure with the bandage. In the more chronic forms of the affection the different preparations of iodine must be brought into play, particularly Lugol's solution, Donovan's liquor, and the various forms of mercury, as the bichloride and biniodide; along with the topical applications just mentioned, if the induration be external. Friction and the cold douche will also prove serviceable under such circumstances.

SECT. III.—TRANSFORMATIONS.

The human body is in a state of constant mutation, decay and renovation, commencing before birth, and continuing down to the last moments of existence. The Wolffian bodies and the gubernaculum of the testicle disappear druring intra-uterine life; then thymus gland is gradually effaced during childhood; the arteries calcify in elderly persons; and at every period of life various states of the system, dependent upon disease or accident, arise, in which there is a strong tendency to the deposition of oil globules, or the transformation of different organs and tissues into fatty matter.

The most important of these changes, surgically considered, are the cellular, mucous, cutaneous, fibrous, calcareous, and fatty; they are all connected with defective vitality, and with atrophy of some, if not all, of the constituent elements of the affected structures.

The *cellular* transformation is met with chiefly in parts that have been rendered useless, either by the natural cessation of their functions, or by accidental circumstances. Thus, the thymus gland, which is evidently connected with some important office in the fœtus, gradually decays during childhood, and is ultimately converted into shreddy cellular substance, of which hardly any trace remains after the thirtieth year. The gubernaculum undergoes a similar change; the gall-bladder, occluded by biliary concretions, is occasionally completely transformed into this tissue; and the cellular adhesions so often seen between the costal and pulmonary pleuræ, consequent upon the degeneration of old, adventitious membranes, are familiar to every pathologist. Various ligaments, especially the capsular, sometimes degenerate in this way, the metamorphosis being most marked in young subjects affected with unreduced dislocations of the hip and shoulder.

When *skin* is inverted for any length of time into one of the natural outlets of the body, as, for instance, the anal, it gradually undergoes a species of metamorphosis into mucous membrane. The first indication of the change is a softened condition of the cuticle and the disappearance of the hair; the epidermis scaling off, the surface beneath assumes a reddish, velvety aspect, becomes extremely vascular, and soon begins to secrete a thin, ropy, whitish fluid, not unlike mucus.

A change from *mucous* membrane to skin is sometimes observed, although the occurrence is uncommon. It is noticed chiefly in prolapse of the rectum, vagina, and uterus, the mucous investment of which, from long exposure to the atmosphere, becomes dry, rough, and insensible, and is ultimately converted into a tissue bearing a more close resemblance to the cutaneous than to the mucous. The transformation, however, as in the case of the skin, is at best extremely imperfect, and it remains to be shown whether, in

either instance, the old structures are so completely deprived of their identity as to justify the idea of a genuine transformation.

The *fibrous* transformation is most commonly met with in those parts of the body that have been deprived, either accidentally or otherwise, of their natural functions. Thus, in an artery that has been tied for the cure of aneurism or the arrest of hemorrhage, the portion of the vessel included between the ligature and the first large collateral branch is gradually converted into a solid cylinder, which, in its turn, is changed into a dense fibrous structure, in which it is impossible to discern any trace whatever of the primitive tissues. Ligaments, serous membrane, and adventitious textures occasionally undergo similar changes. The cornea, in the withered and atrophied eye, the victim of destructive inflammation, is, at times, almost completely transformed into a substance bearing the closest resemblance to the sclerotica, one of the best examples of the fibrous tissue. In some of these cases, as in the one just mentioned, the change is accompanied by a deposit of oil globules. The whitish opaque bodies, so common in the coats of the spleen, in the placenta, and in the arteries of elderly subjects, are apparently essentially composed of fibrous substance, although in their outward characters they strikingly resemble fibro-cartilage.

The *calcareous* degeneration is most common in the arteries, but is also occasionally seen in other parts of the body, as in fibrous tumors, especially those of the uterus, in the articular cartilages, and in the concretions that are sometimes found in the larger joints, particularly that of the knee. In the arteries it generally begins in the form of little opaque patches in the middle tunic, which, as they advance in age, assume a firm, solid consistence, and ultimately convert the vessels into rigid earthy cylinders. The deposit—for such it is, rather than a genuine degeneration—was formerly supposed to be of an osseous character, but that this is not the case is shown both by its chemical and physical properties. In the more matured specimens it is essentially composed of carbonate and phosphate of lime, in union with a minute portion of albumen; in recent cases, on the contrary, the animal matter exists in much greater quantity. It differs still further from bone in having no areolar structure, and in being destitute of vitality. In fibrous tumors of the uterus large calcareous masses, weighing several pounds, are occasionally found.

The *fatty* degeneration, if not the most common of all, is the most universally distributed, since there is hardly any organ or tissue of the body in which, under favorable circumstances, it may not occur. Observation has shown that it may take place even in the lungs, in cartilage, in bone, in the placenta, in the cornea, and in the crystalline lens. It is also met with in plastic exudations, tubercle, morbid growths, and in pus globules. It is of frequent occurrence in the muscles, and in the coats of the arteries, in connection with the atheromatous deposit. In short, it may take place both in natural and in adventitious formations, in the hard as well as in the soft, in the most humble as well as in the most exalted in point of organization and life-power. Of all the various structures, however, which are liable to suffer from it, the liver and the arteries are the most frequently affected. Fatty degeneration may occur in the former at any period of life, even in young children, and is a very common consequence of habitual alcoholic stimulation; in the latter, on the contrary, it is usually restricted to elderly subjects. The senile arc of the cornea is most common in advanced life, and is supposed by some observers, amongst others by Mr. Canton, to be almost always coincident with fatty degeneration of the heart and other organs. Fatty degeneration of the muscles occurs both in the voluntary and involuntary classes, although it is by no means so common in the latter as in the former.

The fat in this degeneration occurs either in the form of a drop of oil or of small granules in the cells of the tissues, their protoplasm being converted by chemical decomposition into fat. Such an infiltration is often observed in the liver, brain, pancreas, and arteries.

An organ that has undergone the fatty degeneration is generally a few shades lighter than in the natural state, diminished rather than increased in consistence, easily torn, greasy to the touch, and of less specific gravity than in health. The amount of oil which it contains often ranges from one-third to one-half of its own weight.

What is the essential cause of the fatty degeneration? In some cases it is evidently connected with a general hypertrophy of the adipose tissue, accompanied by a redundancy of oily matter dependent upon the use of an inordinate quantity of hydrocarbonaceous food and imperfect assimilative power. In the liver of some of the inferior animals the fatty degeneration may often be produced at will, simply by subjecting them to rest, and constantly cramming the stomach with food, which, by creating obstruction in the portal circle, probably induces congestion and inflammation of the hepatic tissues, which thus

favor the deposition of oily matter. The fatty transformation of the liver of drunkards is doubtless occasioned in a similar manner. In other cases the lesion appears to be essentially due to a want of exercise of the affected parts, conjoined with deficient nervous and vascular supply, as is so often witnessed in the muscles of the leg in paralysis of the inferior extremity. Under such circumstances, especially when the case is of long standing, the muscles generally assume a pale, yellowish, or brownish aspect, are remarkably soft and flaccid, and yield a clear oily fluid on pressure, their fibres, however, remaining perfectly distinct.

The treatment of the fatty transformation is unsatisfactory. When the patient's habits are at fault, they must of course be corrected; alcoholic stimulation must be abandoned, the diet must be changed, and a system of exercise must be instituted, to improve the state of the blood and the assimilative powers. Local treatment should not be neglected when the degeneration is suspected to be going on externally, as when the muscles of a limb begin to waste in case of paralysis, disease, or injury.

The *lardaceous* degeneration has been described under various names, as amyloid, waxy, and albuminoid. Its clinical history is still imperfectly understood, although its origin, as is well known, is usually associated with a depraved condition of the system, of which pulmonary phthisis, Bright's disease, syphilis, carcinoma, chronic alcoholism, and affections attended with profuse suppuration, are among the most common and prolific causes. The degeneration is generally widely diffused, but the structures which are more particularly liable to suffer are the liver, spleen, kidneys, lymphatic glands, blood-vessels, muscles, and cartilages. The muscular tissue of the smaller arteries is, apparently, its primary seat. Virchow has seen cases in which the minute arteries of the alimentary canal from the mouth to the anus were literally loaded with amyloid matter. It has also been noticed in false membranes, in recent fibrinous exudations, in tubercle, and in carcinomatous formations of the liver.

An organ affected with the amyloid degeneration is deficient in potassa and phosphoric acid, while it contains an unusual quantity of soda, chlorine, and cholesterine; is increased in volume, consistence, and weight, absolute and specific; feels like a piece of soft wax, or wax and lard combined; and exhibits upon its cut surface a semitransparent appearance, the more delicate sections being perfectly translucent. The coats of the arteries, at first opaque, thickened, and granular, eventually become pellucid, transparent, and hyaline, at the same time that they are diminished in caliber, and so much increased in firmness as to remain patulous when divided.

Lardaceous matter, regarded by some as dealkalized fibrin, has a strong resemblance to albumen, but differs from it in its insolubility in acids containing pepsin. Water, alcohol, and alkalies produce no change in it. The contact of iodine causes a reddish-brown color, characteristic of its nitrogenous nature. The matter seems to pass from the vessels in a fluid state, coagulates firmly in the living structures after it is effused, and is entirely destitute of cell properties. The only form in which it occurs is that of an infiltration, which is often so great as to inundate the tissues in which it is deposited.

The lardaceous degeneration is characterized by a pale waxy appearance of the skin, by anemia, and by progressive emaciation and debility. Its immediate effect is to diminish the lumen of the minute vessels, and thus to interfere with the process of nutrition and repair. Of the immediate cause of the degeneration nothing whatever is known, and of its treatment we are equally ignorant.

The *pigmentary* degeneration occurs principally in the skin, lungs, and lymphatic glands, in certain morbid growths, especially warts and nevoid tumors, and in melanotic carcinoma and sarcoma. The scars of old ulcers of the legs are frequently of a bluish, pink, bronze, or brownish tint, evidently the effect of some abnormal deposit. The lungs in spurious melanosis, as it is termed, so common among colliers, often become remarkably black from the inhalation of carbonaceous matter in an extremely finely pulverized state, and the bronchial lymphatic glands not unfrequently suffer in a similar manner. In Addison's disease of the suprarenal capsules, a bronzed appearance of the skin was at one time regarded as a diagnostic sign of that affection. In melanosis the black color is characteristic of that peculiar formation. Sarcomatous growths are often stained with pigmentary matter; and the so-called analogous tissues occasionally experience similar changes. The pigmentary degeneration is generally denotive of diminished vitality, and no treatment, so far as is at present known, exercises any influence over it.

SECT. IV.—HYPERTROPHY.

The word hypertrophy is employed to designate the increased size and weight which an organ acquires in consequence of an augmentation of its nutrition or of chronic irritation. The hypertrophy may be general or local, and the latter may affect either an entire organ, or be limited to particular portions of it, or even to some of its component elements. It may exist alone or in association with other lesions, and is liable to occur at all periods of life ; sometimes, as in the thymus gland and capillary vessels, apparently even before birth. No organ or structure is probably entirely exempt from it ; but among those which most frequently suffer are the lymphatic glands, mamma, thyroid body, spleen, liver, heart, prostate gland, tonsils, bones, vessels, adipose tissue, and skin. The best example of hypertrophy of the cutaneous textures is elephantiasis, in which the increase of weight and bulk is sometimes enormous.

The causes of hypertrophy are, first, inordinate exercise of the organ ; secondly, mechanical obstruction; and, thirdly, chronic inflammation.

The most simple manner, apparently, in which hypertrophy of an organ occurs is from an increase of its functional activity. Examples of this variety of the affection are found in various textures, particularly the muscles, lungs, and kidneys. The muscles, voluntary and involuntary, are always developed in proportion to the amount of their exercise. Kept at rest, they soon lose their firmness and healthy color, and become comparatively feeble and useless. The blacksmith, who constantly plies his hammer, has much larger and stronger arms than the dancing-master, who merely employs his legs. The same law obtains with regard to the lungs and kidneys. When one of these organs is imperfectly developed, compressed by effused fluid, or destroyed by some morbid growth, the other is sure to become preternaturally expanded, thereby compensating for the deficiency. There are certain viscera, as the uterus and breast, which are subject to temporary hypertrophy. During pregnancy and lactation these organs increase very much in bulk, but again diminish soon after parturition and weaning.

Hypertrophy may be caused, secondly, by some mechanical impediment interfering with the due performance of the functions of an organ. This is frequently seen in the heart, where, from disease of the valves, preventing the easy passage of the blood, the viscus is obliged to perform increased labor, and so becomes more or less enlarged. In the muscular fibres of the stomach, a similar change is often witnessed from obstruction at the pylorus, and in those of the urinary bladder, from stricture of the urethra, or hypertrophy of the prostate gland.

Hypertrophy from chronic irritation is of frequent occurrence, and is met with under a great variety of circumstances. Some of the best examples of this species of hypertrophy are seen in the lymphatic glands of the groin from chronic irritation of the head of the penis, of the mesentery from ulceration of the ileum, and of the bronchiæ from disease of the lungs. Enlargement of the liver and spleen, sometimes of enormous size, is unquestionably due to a similar cause. In chronic dysentery, not only the mucous and submucous connective textures become hypertrophied, but the affection often extends to the muscular tunic, which occasionally attains an extraordinary degree of development. The follicles and villosities, which, in the healthy state, are hardly perceptible to the naked eye, are also rendered extremely prominent, the former being sometimes of the size of a mustard-seed, while the latter are more than a line in length. A similar development is frequently observed in the coats of the urinary bladder, as a consequence of chronic inflammation.

The color of the affected organ is generally much heightened, especially when the hypertrophy is wholly physiological ; on the other hand, it is occasionally greatly diminished, and instances are observed in which it is apparently perfectly natural. The consistence may likewise be normal, diminished, or increased. These three conditions do not, however, occur with equal frequency. An increase of density is by far the most common, and is particularly conspicuous in hypertrophy of the heart, the mammary gland, the muscular fibres of the bladder, the lymphatic glands, connective tissue, bones, liver, spleen, and kidneys. A diminution of consistence is extremely rare, and cannot be viewed as a necessary consequence of the lesion.

An increase of weight of the affected organ follows, as a natural effect, when the lesion is not conjoined with atrophy. An augmentation of volume is by no means constant. Thus, in hypertrophy of the heart and bladder, there may be great development of the muscular fibres, with marked diminution of the size of their cavities. A change of form

always arises when hypertrophy is circumscribed, or limited to a particular point, as in the bones, skin, heart, bronchial tubes, and bloodvessels.

Hypertrophy essentially consists in an augmentation of the nutritive function. Whenever an organ is unusually active for any length of time, a much greater quantity of blood is sent into it than in the natural state, and it assumes a deeper color in consequence, at the same time that its structure is rendered more dense, and its cells multiply and increase in size. It is in this manner that the alteration under consideration is brought about. In that variety of it which results from chronic irritation, it is not unlikely that there is often superadded to the alteration just mentioned a deposit of new substance in the connective tissue, thus leading to an actual change of structure. The effects of hypertrophy on surrounding parts will be considered in connection with the different organs and textures of the body.

In regard to the treatment of hypertrophy, no definite rule can be laid down, as it must be regulated, in great degree, by the nature of the exciting cause, which should, therefore, always be a prominent object of inquiry. Much benefit may generally be anticipated from the steady and persistent use of sorbefacients, locally and constitutionally applied, such as iodine, blisters, compression, mercury, iodide of potassium, and tartar emetic, aided by purgatives and attention to diet. In some cases, nothing short of the removal, partial or complete, of the affected organ holds out any prospect of relief.

SECT. V.—ATROPHY.

Atrophy, the reverse of hypertrophy, consists in a wasting of the substance of an organ, accompanied by a diminution of its weight and bulk. Occurring at all periods of life, it may affect an entire organ, or a part of an organ, or be limited to some of its constituent elements.

Remarkable examples of general atrophy are occasionally met with, but as such an occurrence is of no special surgical interest, it does not demand any particular notice here. Cases of this kind are sometimes apparently of a congenital character; at other times they are the result of disease, and are either curable or otherwise, according to their extent and the nature of their exciting causes.

Local atrophy may be produced by a variety of causes, of which the principal are, first, cessation of the natural function of an organ; secondly, loss of nervous influence; thirdly, deficient supply of blood or nutritive matter; and, lastly, inflammatory irritation.

It is a law of the animal economy that an organ, deprived of its natural functions, gradually falls into a state of decay. Of this class of structure are the umbilical vesicle and the pupillary membrane of the fœtus, the former of which, after having subserved its purpose, disappears at the close of the third month; the latter between the seventh and eighth. The development of the genito-urinary organs is preceded by the formation of two small jelly-like glands, known as the Wolffian bodies, which acquire their greatest bulk about the middle of utero-gestation, after which they gradually shrink, and at length entirely disappear. The gubernaculum, first visible in the tenth week of embryonic life, is a thin, membranous process, which guides the testicle to the internal ring, and is eventually converted into cellular substance. All these are instances of atrophy from the cessation of the functions of an organ in the fœtus. After birth, changes not less remarkable are observed; such, for example, as the wasting of the thyroid body, the suprarenal capsules, and the thymus gland. From the same cause the alveolar processes of the jaws disappear after the removal of the teeth. The ovaries shrink after the decline of the menses; and, in conformity with a similar law, the testicles often diminish remarkably in size in monks, who lead a life of celibacy, in the strict observance of their vows.

Atrophy may, secondly, result from a diminution of nervous influence; a circumstance not surprising when it is recollected how much the action of the capillaries is under the control of the cerebro-spinal axis. Whole limbs sometimes waste from this cause; in other cases the lesion is more limited, and implies only a very partial disorder of the nerves. Atrophy caused by disease of the brain occurs much more slowly than when it is occasioned by an affection of the nerves of the part.

This variety of atrophy is very common in young children during dentition, from the sudden suspension of nervous influence, causing a species of local paralysis, which often terminates in complete wasting of the affected parts. It is most frequently observed in the lower extremities, sometimes in one, at other times in both; but it also occurs in the upper extremities, particularly in the deltoid muscle, which is occasionally transformed into a pale, flabby, membranous layer, hardly a few lines in thickness.

Great atrophy of the upper extremities occasionally occurs from pressure of the head of the humerus, as in dislocations, on the axillary plexus of nerves, thereby interrupting the nervous influx. When such an accident arises in a very young subject, the growth of the limb, if not positively arrested, is imperfectly executed, and not only the muscles, but even the bones, become singularly stunted in their development, their shafts being very thin, and their prominences unnaturally small and indistinct.

A mere perversion of the nervous function of an organ is capable of producing atrophy. In neuralgia of the testicle that organ is sometimes remarkably diminished both in size and consistence, not so much, apparently, from an actual loss of nervous influx, as from a change in its character. What corroborates this view is that the testicle, during the wasting process, is often so exquisitely sensitive as to be intolerant, of the slightest manipulation.

The effects of a deficient supply of blood in producing atrophy are well known. When any part is deprived of the usual quantity of this fluid, it very soon becomes enfeebled, its substance is rendered pale and flabby, and it at last loses its functions, although every other condition for their performance may remain unimpaired. Thus, the testicle wastes after tying the spermatic artery; and, for the same reason, the muscles of the lower extremity occasionally shrink after ligation of the principal vascular trunk of the thigh. Atrophy of the heart is sometimes produced by ossification of the coronary vessels; and a case is recorded in which the spleen, from the obstructed condition of its artery, was not larger than a filbert. In old age, many of the capillaries are obliterated; and it is not improbable to this circumstance is owing that diminution of the size of the organs which constitutes senile atrophy. To the same cause is to be attributed the wasting of the lung and heart, from the accumulation of fluids in the pleural and pericardiac cavities.

Atrophy attendant upon mere want of exercise is probably essentially due to deficient nervous and vascular supply, in conformity with a law, mentioned under the head of hypertrophy, that the development of an organ is usually in proportion to the amount of its use. The wasted and attenuated condition of the legs in club-foot and other affections depriving the muscles of their functions, or interfering with their proper exercise, is probably owing entirely to this cause, as is shown by the fact that, when the disability is removed, the individual gradually recovers the functions of his limbs, the calves often becoming strong and plump, as if there never had been any arrest of growth. The only, or chief, exception to this is where the muscles have undergone the fatty degeneration, when they never regain their original development, but always remain weak and puny.

Atrophy from the effects of inflammation is very common. A good example of this is seen in the wasting which occurs in the gall-bladder from the presence of biliary concretions, in which this organ is sometimes reduced to a mere little fibrous mass, with hardly any trace of the original reservoir. Hepatitis often gives rise to atrophy of the parenchymatous structure of the liver, and orchitis, especially when the result of mumps, is not unfrequently succeeded by impotence. How the lesion, in these and other cases, is produced, is not easily determined. It is probable that the inflammatory deposits may so choke up the capillary vessels of the parts as to deprive them of their customary and necessary supply of nutritive material; or, if this conjecture be untenable, that the pressure exerted by these effusions causes the absorption of some of the anatomical elements of the affected structures, thus reducing them, as it were, to their primitive condition.

Atrophied structures are prone to undergo the fatty transformation, and it is not improbable that this transformation itself occasionally acts as an exciting cause of the wasting process. However this may be, it is certain that the two lesions are sometimes so intimately associated together as to render it impossible to determine which preceded the other, or what part they played as cause and effect.

The change of color experienced by an atrophied organ is necessarily greatly influenced by the natural complexion of the part, but does not possess any special surgical interest. The weight of the affected structures is generally considerably diminished, but their bulk often remains unaltered, and it is not uncommon to meet with cases where it is even greater than natural.

The treatment of atrophy, occurring in an external or accessible part of the body, as a muscle, resolves itself into the use of the warm and cold douche, frictions, either dry or through the medium of stimulating embrocations, shampooing, massage, and the application of electricity, as described under the head of wasting palsy. The general health must be amended, strychnia and tonics being given when there is marked evidence of debility. The affected part must be gradually and steadily exercised, or, as it were, re-

educated : the influences of a strong will frequently directed upon it being often of essential service in rousing its latent faculties.

SECT. VI.—CONTRACTION AND OBLITERATION.

By the word contraction is meant the diminution of a canal, tube, or passage to an extent incompatible with the due performance of its functions. It is strictly synonymous with the term stricture, the signification of which is so well understood by the surgeon. The lesion is liable to occur in various degrees, from the slightest possible change in the size of a canal to the complete obliteration of its caliber.

The chief interest of this subject, surgically considered, relates to the contractions that occur in the mucous canals, or excretory ducts, as they are called, and the bloodvessels, in both of which the lesion is frequently productive of the most disastrous consequences; attended, in the former, by retention of the secretions of these tubes and of the contents of the reservoirs with which they communicate, and in the latter by an impediment to the circulation which, in one case, may lead to atrophy, and, in another, to softening, ulceration, or gangrene.

Contractions of the mucous passages, to which the ensuing remarks are more particularly designed to apply, are deserving of great attention, both from the frequency of their occurrence, and from the great suffering which they so often entail upon those who are the subjects of them. They are met with in nearly every mucous outlet of the body, but are more common in the male urethra and in the nasal canal than anywhere else. Doubtless stricture often exists in the smaller excretory ducts, as those of the prostate and salivary glands, without our knowledge, or without awakening any serious functional disturbance ; in the larger passages, on the contrary, the slightest coarctation is generally a source of more or less annoyance, if not of great pain and inconvenience.

The causes of contraction are mainly two ; inflammation with plastic deposit, and mechanical compression, the former being by far the more common.

The inflammation giving rise to this lesion may be either acute or chronic ; in the former case generally doing its work rapidly, with bold and well-marked symptoms ; in the latter, on the contrary, the injury is often inflicted in a slow and stealthy manner, without perhaps exciting any suspicion as to what is impending. The plastic matter, the real cause of the contraction, is generally deposited in the submucous connective tissue, either exclusively, or partly there and partly in the interstices of the mucous membrane itself. However this may be, it soon becomes organized, and is ultimately transformed into cellulo-fibrous, fibrous, or fibro-cartilaginous tissue, which, gradually contracting upon itself and upon the neighboring structures, thus diminishes, in a proportionate degree, the caliber of the tube in which it is situated. It is in this manner that all organic strictures, properly so termed, of the mucous outlets of the body are formed.

The second cause of contraction is of a purely mechanical character, although in most cases, if not in all, the lesion is attended with inflammation and plastic deposit, secondary, however, in their character. It is thus that stricture of the nasal canal may be produced by the pressure of a tumor in the sinus of the upper jaw ; of the bronchia, by the pressure of an aortic aneurism ; and of the Fallopian tubes, the biliary ducts, and the uterus, by the pressure of an enlarged viscus or a morbid growth in their immediate vicinity. The same cause often induces constriction and even complete obliteration of the bloodvessels. A tumor, compressing the aorta, has been known to give rise to permanent closure of that vessel as effectually as if it had been surrounded by a ligature.

The extent of the contraction varies, both in length and diameter, in such a manner as to render it impossible to specify it in a general manner. In some cases it may not exceed the fraction of a line, while in others it may involve the whole length of the affected tube.

The effects of such a lesion upon the parts concerned are often extremely distressing. Thus, in the urethra, the obstruction is attended with difficulty of micturition ; in the nasal canal, with impediment to the passage of the tears into the nose ; in the œsophagus, with difficulty of deglutition.

The prognosis is, ordinarily, not at all serious, as the obstruction generally admits of relief, except when it has been induced by the compression of some internal tumor of an enlarged viscus, when it will almost necessarily be irremediable.

The treatment of the inflammatory form of contraction must be conducted according to the general principles laid down in the chapter on the exudation of plasma ; by antiphlogistic remedies in the earlier stages of the disease, and afterwards by alterants, rest,

light diet, purgatives, leeches, and a regular, systematic course of dilatation by means of bougies, either alone or aided by incision, scarification, or free division of the affected structures. Great care must be taken, in the employment of dilatation, to conduct it in the most gentle and cautious manner, as the object is to excite the absorbent vessels, and at the same time to keep the capillaries, if possible, in a perfectly passive condition. In this way riddance is eventually effected of the effused matter, upon the presence of which the constriction essentially depends, without the risk of provoking further inflammatory deposits.

SECT. VII.—FISTULES AND SINUSES.

A fistula is a narrow track, straight or tortuous, of variable depth, having generally two distinct orifices, lined by an adventitious membrane, and bathed with a thin, gleety fluid, intermixed with the natural contents of the part, organ, canal, or cavity affected. The disease, which is always of a consecutive nature, occurs in different regions of the body, and is developed under the influence of various causes.

Although the abnormal track has usually two openings, one of which is superficial and the other deep-seated, yet this is by no means constantly the case. Hence the distinction of fistules into complete and partial. The terms recent and old, often used by writers, refer merely to the duration of the disease.

The lesion may occur in almost any situation, but originates most frequently about the anus, perineum, face, groin, and mammary gland. Fistule of the neck, thoracic cavity, the biliary apparatus, the stomach, colon, and small bowel, kidney, pancreas, and urinary bladder, is comparatively rare. It takes place in both sexes and at every period of life; but children and young persons suffer much less frequently than the old and middle-aged.

The nomenclature of fistule is quite extensive. The names are derived either from the parts in which the abnormal passage is situated, as anal, perineal, broncho-pleural, and recto-vaginal, or from the nature of the discharge, as salivary, urinary, and sterco-raceous.

Fistules vary much in their extent. The longest tracks occur along the spinal column in connection with psoas abscess. In this affection, the matter generally escapes at the groin, just above Poupart's ligament, in the upper part of the thigh, or, lastly, in the ileo-lumbar region, the channel which is thus established varying in length from six to twelve inches, and being always lined by a well-organized, adventitious membrane. Passages of considerable length are sometimes met with in the internal organs, as between the kidney and lung, between one coil of intestine and another, or between the urinary bladder and the cutaneous surface. In other situations, on the contrary, the track is remarkably short, being hardly two or three lines from the surface, or from the cavity with which it communicates.

The diameter of these abnormal tracks is also very variable. Sometimes they are so small as scarcely to admit the finest bristle; while at other times they are sufficiently capacious to receive a goose-quill or the end of the finger. The narrowest tracks usually occur in the lachrymal passages, salivary glands, anus, and perineum. It is not often that a fistule is of the same uniform diameter throughout; on the contrary, it is almost always larger at one point than at another.

The external orifice, generally of a rounded or oval shape, may be so narrow, on the one hand, as to be hardly perceptible; or, on the other, so large as to admit the end of a probe, a goose-quill, or a finger. It may have sharp and well-defined margins; be surrounded by a soft, spongy, florid rim; or be depressed, inverted, or infundibuliform. The number of external orifices varies in different cases, from one to as many as six, ten, or even a dozen; when it is very considerable, the affected surface commonly presents a cribriform appearance.

The internal orifice may be of the same size as the external, or it may be smaller or larger. In its shape it is usually irregularly rounded, and it is seldom that it is found multiple, even when the number of external openings is considerable.

Although the direction of the passage may be perfectly straight, yet, in general, it is more or less flexuous, serpentine, oblique, or winding. Occasionally it forms nearly a right angle with the surface upon which it opens. When several tracks exist, they often run together, and terminate, by one common orifice, upon the reservoir with which they communicate.

A fistule, in its recent state, is simply a raw surface bathed with purulent matter. It is, in fact, an ulcer, an open sore, a solution of continuity, which must undergo a pro-

cess of repair before it can justly be entitled to its distinctive appellation. The track, however, soon becomes smooth, and is speedily coated with an adventitious membrane, varying in thickness from a mere film to half a line, a line, or even the sixth of an inch. The new layer, at first soft and easily detached, gradually augments in density, and is at length inseparably united to the parts which it serves to line. Its color, like its consistence, is very much influenced by its age, and by the nature of the secretion or excretion which passes over it. In its earlier stages it is red, pink, or rose; in cases of long standing, white, gray, or slightly bluish. The free surface of the membrane is smooth and polished; or it is rough, mammillated, or studded with villi of various shapes and sizes. The other surface is attached by means of dense connective tissue to the parts upon which it lies. Bands of lymph sometimes extend from one side of the abnormal channel to the other, very much as in the bridle stricture of the urethra.

The membrane here described is formed out of the blood-liquor, and is of the same nature as the pyogenic membrane of a chronic abscess. Around the anus, in the perineum, and in some other regions, it bears no little resemblance to mucous tissue, but differs from it in having no follicles and no distinct epithelial layer. It is liberally supplied with vessels, nerves, and, probably, also with absorbents, is the seat of a constant secretion of gleety or other matter, and is liable, like all new textures, to inflammation and its consequences. In ancient cases it occasionally acquires a dense, fibrous, or fibro-cartilaginous consistence.

The nature of the discharge in this disease varies with the situation of the abnormal passage. In general, it is thin and gleety, as in chronic gonorrhœa, and mingled with the natural secretions or excretions of the reservoir with which the fistule communicates. When, however, the lining membrane labors under inflammatory irritation, the discharge is either entirely suspended, or it is bloody, purulent, or muco-purulent.

The parts in which the abnormal track is situated are variously affected, being sometimes nearly natural, but more generally firm and callous, from the effusion and organization of plasma, which, when present in large quantity, often completely obliterates the meshes of the connective tissue. Owing to this condition, many of the smaller vessels are choked up, while those which remain are, when divided, unable to retract, thus becoming not unfrequently a source of considerable hemorrhage.

The causes of fistules are either mechanical or vital. To the first class belong wounds, contusions, and lacerations; to the second, ulceration, gangrene, and abscesses. There is a variety of the affection which may be regarded as a remnant of embryonic organization. Its most frequent situation is the antero-lateral part of the neck. Like the ordinary fistule, it may terminate in a cul-de-sac, or it may have two orifices, of which the external is sometimes scarcely visible. The abnormal passage itself is usually very narrow, and seldom extends beyond two or three lines in depth.

The treatment of fistule must be regulated by circumstances. In recent cases, before the passage has become lined by an adventitious membrane, a cure will sometimes follow the use of stimulating injections, as a weak solution of nitrate of silver, sulphate of copper, tincture of iodine, or acetate of lead, repeated twice in the twenty-four hours; or by touching the parts lightly once a day, or once every other day, with solid lunar caustic, or with the end of a probe dipped in a solution of acid nitrate of mercury. Strict attention should be paid to cleanliness, and the parts should be maintained in a state of absolute rest. It is seldom, however, that a permanent cure can be effected in this way, especially if the fistule be of any extent, or situated where it is influenced by the contraction of muscular fibres, as, for example, when it involves the anus. The best plan, in fact, nearly always is not to lose any time in vain experiments with these remedies, but at once to lay open the abnormal passage in its entire length, so as to afford the parts an opportunity of healing from the bottom by the granulating process, a tent being interposed between the edges to prevent their readhesion. Occasionally a seton may be passed through the track, and retained until it ulcerates out. In some forms of fistule, as in the vesico-vaginal and urethral, a very delicate operation is generally required in order to effect a cure, consisting in paring the margins of the opening and in bringing them together by the interrupted suture.

The healing of a fistule is often materially retarded, if not effectually prevented, by the presence of foreign matter, as a mass of dead connective tissue, a loose piece of bone, a bullet, or a portion of wadding, or, by the contact of some irritating substance, as urine or feces. The indication, of course, is to remove the extraneous matter, whatever it may be, and then to manage the case upon the principles just laid down.

Occasionally, again, the reparative process may be opposed, at least in part, by deficient tone of the system, or by some disorder of the general health. The patient, for example, may be anemic from organic disease, intemperance, or want of wholesome air and food. Such cases, which are not uncommon in large cities, and in the wards of crowded, ill-ventilated hospitals readily suggest their own treatment.

The practitioner is sometimes sorely perplexed in this disease as to whether he should attempt a radical cure, or limit his efforts to palliative measures. In general, it will be best to let each case be governed by its own rules. When the fistule has been of long standing, and has acted all along as a drain upon the system, serving perhaps to counteract some other affection, such as phthisis or a tendency to apoplexy, no operation should be practised, since it could hardly fail to provoke mischief. In fact, serious organic disease of any kind is a contraindication to an operation. The only exception to this is where the fistule is a cause of excessive local distress, completely depriving the patient of sleep, appetite, and comfort. Under such circumstances, the surgeon could hardly refuse his aid; but, before doing this, he would be sure to open a new source of counter-irritation, in the form of an issue or seton, in some other and more eligible portion of the body, thus establishing a drain at least equal to that which he is about to suppress, as a means of temporary mitigation. In ordinary cases there is of course no reason for delay; the operation is promptly performed, and a rapid recovery is reasonably anticipated.

CHAPTER VI.

CONGENITAL MALFORMATIONS.

CONGENITAL malformations, surgically considered, constitute a subject of the deepest interest, both because they are of frequent occurrence, and because they generally require an extraordinary amount of knowledge and skill for their successful management. Presenting themselves under different forms or characters, they exhibit every variety of grade, from the most simple departure from the normal standard to the most pitiable and disgusting deformity, well calculated to elicit the sympathy and aid of the considerate and humane surgeon. With a view to a more full appreciation of the nature of these malformations, they may conveniently be arranged under the following heads: 1st, deficiency of parts; 2dly, redundancy of parts; 3dly, displacements; 4thly, occlusions; 5thly, deviations of positions; 6thly, adhesions of contiguous surfaces; 7thly, vascular tumors.

1st. The first class, consisting of a *deficiency* of parts, may be subdivided into two orders; the one comprehending fissures, or clefts, and the other an entire absence of certain structures, as a finger, hand, or ear.

The most common, and, in a surgical point of view, the most interesting, fissures are harelip, cleft palate, bifid uvula, exstrophy of the bladder, epispadias, hypospadias, and bifid spine, together with extraordinary patency of the fontanelles. Of these malformations some admit of relief by operation, whereas others are hopelessly irremediable; at all events, every attempt hitherto made to cure them has either signally failed, or eventually destroyed the patient. The operation for harelip is of daily occurrence, and, when properly executed, rarely disappoints expectation; besides, if it fail, it admits of repetition. Staphylorraphy has also become a common procedure, which is frequently, if not generally, crowned with success. Exstrophy of the bladder, consisting in a deficiency of the anterior wall of that viscus and of its protrusion at the linea alba, has hitherto, for the most part, resisted every means directed for its relief. Epispadias and hypospadias are difficult of cure; and a cleft of the vertebra, with protrusion of the envelops of the spinal cord and of the cephalo-spinal liquid is nearly always a fatal affection. The closure of these fissures is effected by paring their edges, and approximating them by suture, ultimate union being accomplished through the intervention of plastic matter. The tumor in bifid spine is emptied with the trocar, and then injected with some slightly stimulating fluid, with the hope of exciting obliterative inflammation. In general, the operation is speedily followed by convulsions, coma, and death.

In the second order of cases the deficiency consists in the absence of certain structures, as a finger, a hand, or even an entire arm. The genital organs suffer perhaps more fre-

quently in this way than any other parts of the body. Thus it is by no means uncommon to find the vagina absent, or the vagina and uterus, or these organs along with the ovaries and Fallopian tubes. Sometimes the testes are wanting, or, if present, they exist only in a rudimentary form, perhaps hardly equalling the volume of an ordinary bean. The penis, too, may be absent; or, instead of being large and well grown, it may, at the age of puberty, be less than that of a child at the eighth or tenth year.

2dly. A congenital *redundancy* of structures is sometimes met with, consisting, chiefly, in hypertrophy of the integuments of various regions of the body, or in the addition of a supernumerary finger, toe, tooth, or ear. To the same category belong the anomalous divisions of certain arteries, as the brachial and femoral, high up in their respective limbs. A redundancy of skin and connective tissue is most common about the neck, hands, feet, and genital organs, as the prepuce and vulva, where the superfluous structures sometimes occur in large, pendulous masses. A supernumerary toe, thumb, or finger is no unusual occurrence; occasionally each hand and each foot are provided with such an appendage. I have seen one well-marked example of four ears. An increase of the natural number of teeth is not uncommon. In some of these cases the supernumerary organ is buried in the alveolar process of the jaw, where I have known it to be productive of such an amount of disease as to require a serious operation for its removal. Most of these malformations admit of cure by retrenchment with the knife, and the operation may generally be safely executed at an early age.

3dly. Congenital *displacements* occur in various parts of the body, but principally in the articulations and in the abdominal viscera. The joints which are most liable to this form of dislocation are the hip, shoulder, and wrist; but it has also, although very seldom, been met with in those of the jaw, clavicle, elbow, and knee. The deformity thus produced is often very great, and what aggravates the case is the circumstance that it rarely admits of relief, however skilfully and perseveringly it may be treated. The malformation, as will be shown elsewhere, probably begins at an early period of fœtal life, and goes on gradually increasing until it attains an irremediable stage.

The most common form of displacement of the abdominal viscera occurs in what is called congenital hernia, caused by a want of closure of the inguinal canal during the descent of the testis. The consequence is that, soon after the child has begun to breathe, the diaphragm, pressing the bowels against the walls of the abdomen, forces them down into the scrotum. The portion of tube thus displaced is generally a loop of small intestine, but now and then other organs are pushed down along with it. The most suitable remedy for such a defect is steady compression upon the neck of the hernia by means of a well-adjusted truss, which generally eventuates in an effusion of lymph, and the obliteration of the sac of the tumor.

4thly. Congenital *occlusion* may occur in any of the mucous outlets of the body, but is much more frequent at the anus and genital organs than anywhere else. Closure, properly so called, of the anus may be produced by a continuation of the integument across from one buttock to the other; or it may depend upon the existence of a fold of mucous membrane situated just within the anus, an arrangement not unlike a hymen. In either case, relief may easily be effected by the knife, patency being afterwards maintained by the frequent insertion of the finger. The prepuce is sometimes completely impervious, or, if an opening be present, it answers very imperfectly the purpose of an outlet for the urine. The vagina is occasionally imperforate, being closed by what is termed the hymen; and there is reason to believe that certain forms of sterility are due to occlusion of the uterus, or of the Fallopian tubes.

5thly. Congenital *deviations* of position are infrequent. The most interesting, in a surgical point of view, is the deformity of the nasal septum, which is occasionally so great as to interfere materially with the functions of the nose, one of the anterior nares being sometimes completely occluded by the projection of the partition towards the corresponding side. A simple operation, consisting in the removal of the incurvated portion of the septum, generally effectually relieves the difficulty.

There is occasionally a remarkable congenital incurvation of the penis, disqualifying the organ for the easy and full discharge of its functions. The defect is always associated with hypospadias, and consequent shortening, or imperfect development, of the spongy structure of the urethra. An admirable operation for the cure of this deformity, devised by Dr. Physick, and successfully performed by Professor Pancoast, myself, and others, will be described in the chapter on the genital organs.

Deviation of position is often associated with permanent contraction or shortening of the muscles and tendons, as is seen in club-foot, wry-neck, and analogous distortions. This

class of lesions is one of great practical interest, having opened to the modern practitioner a wide field for the exercise of his ingenuity and skill, as well as of his patience. Taken in hand soon after birth, they may frequently be promptly remedied by the use of the most simple appliances, whereas under opposite circumstances the treatment will generally be very tedious, even if aided by the free division of the affected structures. The rectification of these malformations forms one of the most interesting chapters in the history of subcutaneous surgery, one of the great inventions of modern times.

6thly. Congenital *adhesions* most commonly occur between the fingers and toes ; more rarely between other parts, as the lids and ball of the eye, the ear, and scalp. The uniting medium is generally merely a fold of common integument, the severance of which often effectually releases the parts from their restraint, and restores them to usefulness.

7thly. There is a class of congenital affections, consisting of peculiar vascular tumors known as *nævi*, or *mothers' marks*, occurring in different regions of the body, especially the head and face, and constituting a very interesting and important form of morbid growths. Their composition is variable ; sometimes they are essentially composed of dilated and tortuous capillary veins, connected by areolar tissue ; at other times they are made up mainly of enlarged and diseased capillary arteries ; lastly, there is a third species which seems to partake of the character of both the others, the two sets of vessels being so intimately blended as to render it impossible to determine which predominates.

These vascular growths, however constituted, almost always begin in the substance of the skin, from which, as they augment in size, they gradually extend to the connective tissue beneath ; they are of a soft, spongy consistence, readily receding under pressure, and expanding under mental emotion. Their color is variable ; the venous varieties being usually of a dark purple, and the arterial of a red scarlet hue. The latter are of a truly erectile character, and hence they commonly pulsate, heaving and throbbing synchronously with the contraction of the left ventricle of the heart. The growth of both varieties is generally steadily progressive, and the consequence is that they often acquire a considerable bulk.

Most of these morbid growths readily admit of cure, especially if timeously begun. This may be effected, 1st, by ligation ; 2dly, by incision ; and, 3dly, by escharotics.

In regard to the causes of these various malformations, it would be out of place to institute any special inquiry into them here. Some of them are doubtless owing to an arrest of development, dependent upon defective organization of the germ ; others are probably occasioned by irritation of the nervous centres ; while others, again, are perhaps due to faulty position of the fœtus in the uterus, or violence inflicted upon it during gestation.

CHAPTER VII.

TUMORS OR MORBID GROWTHS.

SECT. I.—GENERAL OBSERVATIONS.

TUMORS may be arranged under two great classes, neoplasms and cysts. The former, which constitute permanent additions, either circumscribed or diffused, to the natural tissues or organs in which they take their rise, are simply pathological new formations, representing an excess of physiological development and growth under perverted functional or nutritive disturbances. Cysts, on the other hand, may be new formations, although they usually originate in other ways.

Morbid growths are now almost universally classified, for the sake of histological uniformity, according to their likeness to, or derivation from, the physiological tissues. Although this classification has been variously modified by different authors, I have, after careful consideration, adopted the following arrangement, which has, at least, the merit of designating the origin of the neoplasms and the tissues of which they are composed :—

I. Cystic tumors in general.

II. Neoplasms in the strict acceptation of the term.

A. Of these, certain ones are derived from and composed of connective tissue and its equivalents, of which two divisions may be made, namely :—

a. Those which represent perfected or matured connective tissues, and which may,

therefore, be termed typical. These comprise lipoma, or fatty tumor; fibroma, or fibrous tumor; chondroma, or cartilaginous tumor; osteoma, or osseous tumor; and lymphoma, or lymphatic gland-like tumor.

ß. Those which represent embryonic, immature, or unripe connective tissue, and which may be termed atypical, as they do not find their analogues in the adult organism. They are limited to sarcoma and myxoma.

B. The second division of neoplasms includes those which are derived from and are composed of higher tissues. These are, first, myoma, or muscular tumor; secondly, angioma, or a tumor composed of bloodvessels; thirdly, lymphangioma, or a tumor made up of lymphvessels; and, fourthly, neuroma, or a tumor composed of nerve tissue.

C. The third and last division of neoplasms comprise those which proceed from, and are formed essentially of, epithelium. Like the connective tissue growths, they may be separated into those that are typical and those which are atypical.

α. The typical epithelial formations embrace, first, papilloma, or papillary tumor, which has its physiological representative in the papillæ of the cutaneous, mucous, and serous surfaces; and, secondly, adenoma, or glandular tumor, which has its physiological type in the secreting glandular organs.

ß. The atypical epithelial new formations are confined to the genus carcinoma, superficial and deep-seated, with its various divisions.

All neoplastic formations, considered in a general point of view, are governed by two great fundamental laws. The first, originally enunciated by J. Müller, of Berlin, teaches that the constituents of all morbid growths have their types, representatives, or analogues in the normal tissues of the organism, either in their embryonic state, or in a state of complete development. The other, enunciated by Virchow, declares that the cellular elements of all neoplasms have their origin in preëxisting cellular structures. That these doctrines are strictly true, all modern pathologists admit; but it is not true, as Virchow asserts, that the cells of the majority of the neoplastic formations are invariably derived from those of the connective tissue. Carcinomatous tumors, for example, owe their origin to abnormal multiplication and extension of epithelial cells, and, as is well known, wandering cells play an important part in the development of morbid growths.

If these doctrines be accepted, it follows, as a necessary corollary, that all tumors must be in great degree, if not entirely, homologous, and, therefore, that the term heterologous is inapplicable. If, however, the entire structure, and not the individual elements, be regarded as the criterion of heterology, the term should be retained, as there are not a few neoplasms which have no analogues among the normal textures. In point of fact, the so-called homologous growths are for the most part so unlike the physiological tissues that the similarity merely amounts to mimicry. Nothing could deviate more from the normal glandular type than carcinoma, the cells of which extend into the surrounding parts in such a way that the picture is entirely unlike that of the tissue from which it is derived. Through the excessive preponderance and peculiarities of form and grouping of the cells of sarcoma a structure is constituted which is not similar to any matured tissue. Hence the carcinomas and sarcomas must be regarded as heterologous growths. It should, however, be stated that the term heterology is employed by Virchow in an entirely different sense, and that his views have met with general acceptance. He teaches that heterology may be applied to the homologous formations in the sense of misplacement, as a fibroma, for example, in a bone; and he says, " Heterologous structures, when considered in reference to their points of origin, may easily be separated from the homologous ones by their deviating from the type of the part in which they arise. When a fatty tumor is met with in adipose tissue, or a fibrous tumor in connective tissue, the type followed in the formation of the new structure is homologous to the type followed in the formation of the old one. All such new growths are included under the term hyperplasia;" and it is a law that hyperplasia produces a tissue similar to that of the original part. " Heteroplasia engenders histological elements which correspond, indeed, to natural forms, but these elements do not arise in consequence of the proliferation of such as previously existed, but in consequence of a change in the original type of the parent tissue." Thus, chondroma of the testicle or of the parotid gland, and osteoma of the connective tissue, are heterologous tumors, since neither cartilage nor bone are normal to these structures. The original unity of all the tissues emanating from the middle leaflet of the blastoderm explains how tumors derived from the connective tissue can transform themselves one into the other; but in such cases we have to deal with a change in the local histological type, which may be expressed by the term metaplasia. From these statements it follows that the same variety of tumor may be homologous or heterologous. A

chondroma, for example, arising from cartilage is homologous, from bone heterologous; an osteoma of a bone is homologous, but heterologous when met with in the brain. In considering, therefore, the question of the homologous or the heterologous nature of neoplasms, attention is not paid to the " composition of the structure as such, but only to the relations which subsist between it and the parent soil from which it springs." Hence the term heterologous may be applied to a tumour when it differs from the tissue in which it is situated; and the terms homologous and heterologous as formerly employed may be substituted by the terms typical and atypical, which I have already used in the classification of neoplasms. By a typical growth is meant one in which a determined model is followed, so that there is a tumor-like reproduction of apparently normal tissues. In the atypical growths the elements are not arranged upon the physiological type, but they deviate in form, size, and grouping from the normal structures, and represent irregular proliferations.

The development and growth of neoplasms depend essentially upon the proliferation of preëxisting cells and their descendants, either through direct hyperplasia and the primary production of the typical forms of the mother tissue, or after the model of embryonic tissue-formation, and their final conversion into the tissue of which the tumor is composed. Having once started, the tendency of the new growth is to persist and increase, either by central growth, that is, by fresh additions through the progressive multiplication of its own cells, as occurs in the perfected histoid tumors, or by peripheral extension or the formation of fresh foci in the contiguous structures, as is witnessed in carcinoma. In the first mode of increase the neoplasm is circumscribed and frequently encapsuled; in the second it infiltrates and destroys the adjacent tissues.

Although the tendency of most neoplasms is to persist unchanged, they are liable to the same diseases as the normal textures, as is evinced by their inflaming, suppurating, ulcerating, and even dying. They are likewise subject to various degenerations and transformations, as the fatty, caseous, mucoid, colloid, cystoid, pigmentary, telangiectatic, calcareous, and osseous. These changes give rise to certain subdivisions, and are often employed as prefixes to indicate the nature of the transformations or degenerations which have occurred, or designate the existence of certain subordinate tissues.

Neoplasms occasionally change their anatomical character, or are converted into tissues of a different kind. Thus, a simple melanoma, or pigmented nævus, may form the starting point for a sarcoma or a carcinoma; a lipoma may pass into a myxoma, or a myxoma into a lipoma, and a fibroma, particularly of the breast, is frequently transformed into a sarcoma.

A morbid growth may be benign or malignant, that is, it may simply incommode by its situation, weight, or bulk, or it may, after a certain period, as the result of its infectious nature, destroy not only the part in which it appears, but also the patient. The neoplasms which evince malignant attributes are carcinoma, sarcoma, myxoma, and certain kinds of lymphoma.

Occurring at nearly all periods of life, and in nearly all the organs and tissues, the malignant and benign formations possess certain features in common with each other; a circumstance which renders it necessary to study them in a general point of view. Such a proceeding, indeed, is indispensable to a correct appreciation of the structure, diagnosis, and treatment of these affections. The principal points to be considered, in connection with these topics are, first, the physical properties of the morbid growth; secondly, its relations to the surrounding parts; and, thirdly, its history.

1. It would be difficult to point out any *situation* in which tumors may not occur. Glandular carcinoma is most common in the mamma, liver, and mucous follicles. Epithelial carcinoma has a peculiar predilection for the cutaneous and mucous textures at the various outlets of the body. Sarcoma is most frequent in the subcutaneous and intermuscular connective tissue, the periosteum, bones, and the salivary and mammary glands. Benign tumors are usually met with in the skin, connective tissue, ovary, uterus, prostate, and nose. Hydatid formations occur chiefly in the liver, breast, testicle, ovary, and bones.

Tumors affect various *forms*, depending upon the nature and amount of resistance offered to their development, and also, in some degree, upon the shape of the parts wherein they originate. A sebaceous tumor is generally globular; a fatty, either flat or pendulous; a polypoid fibroma or myoma, pyriform, conical, or pedunculated. Malignant growths are commonly distinguished by the irregularity of their surface, which is often lobulated, or marked off into ridges and depressions. Certain tumors occur in the form of excrescences, as the warts on the hands of children, the venereal growths on the penis and vulva, and the so-called cauliflower cancer of the uterus.

In their *volume*, tumors range, in every possible gradation, from a millet seed, as in the little granule on the eyelid, to that of the patient's body, as in ovarian cysts and elephantiasis of the scrotum, those enormous masses which are sometimes absolutely more bulky and heavy than the subject in whom they are developed. Fatty, fibrous, cartilaginous, and osseous tumors occasionally acquire a large size, but they are almost the only ones of their class that do. Among the malignant tumors, those which attain the greatest volume are the encephaloid sarcoma and colloid carcinoma; scirrhous, melanotic, and other formations of this description are usually comparatively small.

Tumors vary in *number*; generally they are solitary, but they may be multiple, depending upon their character and the nature of the organ in which they are developed. Osseous, fatty, and sebaceous tumors occasionally exist in large numbers, whereas most of the other innocent growths are commonly solitary. Sarcomatous and carcinomatous tumors are seldom multiple, except in their secondary forms. Tumors that are multiple from their outset are seldom malignant.

With respect to their *consistence*, some tumors are soft, some solid, some semisolid. Tumors containing serous fluid, as hygromatous cysts of the neck and ovary, are always soft and fluctuating, unless they are overlaid by a large quantity of solid substance, when they may partake of the latter character even more than of the former. Fibrous, cartilaginous, and osseous tumors are known by their great hardness, which equals that of the natural structures. Scirrhus is the most firm of the malignant formations, its name being derived from that circumstance. Occasionally one portion of a tumor is soft, another hard, and a third, perhaps, semiliquid. Ovarian growths exhibit these varieties of consistence more frequently, and in a more perplexing degree, than any other, whether benign or malignant.

The *color* of a tumor is generally a matter of secondary consideration, as the morbid growth is seldom sufficiently exposed to admit of direct inspection, except in some of the mucous outlets. In the early stage of all formations of this kind that take place beneath the external surface of the body, there is usually an absence of discoloration, and it is only when the growth bears too heavily upon the integument, pushing it out and stretching it in every direction, or when it manifests a disposition to ulcerate and evacuate its contents, that it renders the skin red, livid, or purple. In tumors of the nose, mouth, throat, vagina, uterus, and anus, color often affords great assistance in the discrimination of the case. A gelatinoid polyp can never be mistaken for a fibrous one, as its complexion is always diagnostic of its character. It may be assumed, as a law, that the lighter a tumor is externally the greater is the probability of its being benign, and conversely.

Mobility is an important quality in a tumor, its amount varying according to the nature of the affected organ and the degree of resistance offered by the surrounding parts. Some morbid growths are never movable, others always are, whatever their age, volume, or situation. A sebaceous tumor never contracts such firm adhesions that it cannot be pushed about; while an exostosis is always immovable from first to last.

Tumors are endowed with various degrees of *sensibility*, depending upon the peculiarity of their structure and the amount of compression exerted upon them by the parts in which they are developed. Most of them, whether innocent or malignant, are free from pain during their earlier stages; but, as they increase in size, they encroach upon the neighboring tissues in such a manner as to interfere with their movements, and thus seriously compress their nerves, whilst the tissues, in their turn, more or less compress the nerves of the advancing mass. Occasionally the pain is characteristic, as, for example, in scirrhus of the mammary gland. Fatty tumors and cystic tumors of the skin are usually entirely free from pain; or, if pain attend their progress, it is the result purely of accidental circumstances. The subcutaneous tubercle is essentially a painful growth from first to last; occasionally the suffering is of a neuralgic character, and extremely distressing by its constancy and severity.

2dly. In regard to the *relations* which tumors bear to the surrounding structures, several circumstances deserve to be noticed. The first is the manner in which they are bound down, or inclosed in their habitation. Every tumor must necessarily have an appropriate residence, but like a settler in a new country, it is seldom content with the spot originally assigned to it. On the contrary, soon lacking room, it encroaches upon, frets, and worries the parts around it, which are not slow to resent the invasion. Mutual oppression and discomfort must be the necessary result of such invasion. For a while the healthy structures successfully resist the intrusion, but as they yield, the enlarging mass often converts the muscles into mere ribbons and the bones into mere shells.

Function, too, may be seriously interfered with; the ranula filling the mouth, the goitre compressing the neck, the myoma occluding the womb.

In the second place, the tumor, as it progresses, is liable, either by its continued pressure upon the overlying parts, or by the gradual decay of its own structures, to produce ulceration, followed by more or less discharge. This tendency, although most conspicuous in the malignant formations, is also witnessed in some of the benign, as the encysted and adipose. Large vessels are sometimes laid open during the progress of the affection, thereby inducing copious hemorrhage.

Tumors often occasion serious disease in the surrounding lymphatic glands. This is particularly true of carcinomatous tumors, in some of which it forms a very conspicuous, if not an unmistakable, feature. Thus, in carcinoma of the tongue, breast and testicle, especially when the disease is fully developed, there is always marked enlargement of the glands, respectively, of the neck, axilla, and groin, either from actual invasion by epithelial cells, or from the effects of sympathetic irritation.

Finally, an intimate *sympathy* exists between tumors and the constitution, operating at one time beneficially, at another prejudicially. The progress of malignant growths is frequently stayed for months and even years, simply by attention to the general health; on the other hand, it is often astonishingly hastened by disorder of the system, and, in fact, by whatever has a tendency to produce derangement of the secretions, especially those of the liver, uterus, and kidneys.

3dly. The *history* of the case often furnishes important points of comparison. Tumors occur at all periods of life, in all classes of persons, and in all varieties of temperament. Certain forms of malignant disease, however, are most common at one period, and others at another. Thus, carcinoma is almost peculiar to elderly subjects, while sarcoma is most frequent between the ages of twenty and forty. The lymphomatous tumor is most common in childhood and adolescence. Benign growths of every description are often observed in early life, some, indeed, being even congenital; but the greatest number by far occur in young adults.

The distinction between innocent and malignant tumors, and between different tumors of the same class, is often extremely difficult, and occasionally, for a time at least, impracticable. For this reason great care and patience are frequently required in order to prevent mistake. Rapidity of growth, great bulk, increase of temperature, a pulpy consistence, firm and extensive adhesions, and early lymphatic involvement, imply inordinate vascularity, and lead to a suspicion of malignancy. There is no tumor, except, perhaps, the round-celled sarcoma, that acquires so large a bulk in so short a time as the encephaloid carcinoma, and there is certainly none that is more surely fatal. Ovarian cysts, of the non-malignant type, often grow very rapidly, and are capable of attaining an enormous size. Sebaceous, fatty, and osseous tumors, on the contrary, usually advance slowly, and occasionally enjoy even a considerable period of repose or inactivity.

Tumors situated immediately over or around an artery generally receive a distinct impulse from the shock imparted to them by the blood. Such tumors, which are very liable to be mistaken for aneurisms, are called pulsating tumors, and are most common in the neck, abdomen, groin, and ham.

The phantom tumor, as it is termed, is only met with in the abdomen, chiefly in nervous, hysterical women, although it is not peculiar to the female sex; and depends, in most cases, partly upon the contraction of the muscles and upon a fat, plump state of the belly, but mainly, and often almost exclusively, upon an accumulation of gas and feces in some particular portion of the bowel, especially the large. The best and surest diagnostic of such a tumor is chloroform, under the relaxing influence of which it always speedily vanishes, the muscles becoming soft and flaccid, and the spine distinctly traceable underneath.

The structures immediately around morbid growths, especially the malignant, and the larger and more rapidly developing innocent, are habitually congested; and hence such tumors are usually a source of great pain and inconvenience. For the same reason operations undertaken for their removal are often unavoidably attended with copious hemorrhage.

It is not often that a tumor disappears spontaneously, although such an occurrence is not impossible; and there are several ways in which it may be effected, as by absorption, enucleation, ulceration, and gangrene. The first of these modes of cure is the most common; and one of the best examples of it is witnessed in the lymphomatous tumor, so frequent in the neck and about the angle of the jaw in strumous children, from exposure to cold and derangement of the digestive organs. The disease essentially consists in an inflam-

matory enlargement of one or more lymphatic glands, which, after having perhaps existed for years, finally disappear without any assignable cause, merely, as it would seem, in consequence of an improved state of the general health, and of a change in the nutrition of the part.

Sometimes a tumor is enucleated, and drops off, leaving perhaps merely its inclosing cyst. It is thus that the fibrous tumor of the uterus is occasionally detached; and a similar accident may happen to an exostosis, particularly if it be large and situated upon the skull. In such cases the vascular connection between the morbid growth and the circumjacent structures is probably, as a preliminary step, in great degree, destroyed, so that the tumor, gradually dying and acting as a foreign body, is at length cast off by the living tissues.

A cure is occasionally effected by profuse suppuration, or, more correctly speaking, by suppuration and ulceration. The kind of tumor most easily influenced in this way is the lymphomatous, which is completely disintegrated and broken down, or it is dissected off by ulcerative action, and is finally detached as an effete substance.

Lastly, gangrene seizing upon a tumor, may so interfere with its circulation as effectually to destroy its vitality. Such an occurrence, although very rare, may take place in a malignant as well as in a benign growth. An elderly lady, a patient of mine, had scirrhus of the mammary gland, which, after having gone on for upwards of a year, was suddenly attacked by gangrene, and in less than a week it dropped off in the form of a black slough, leaving in its stead a large excavated cavity.

It is still a mooted question whether there is a class of tumors intermediate between those so frequently referred to above, to which, scientifically considered, the term semi-malignant is properly applicable. I am not myself inclined to accept such a division; for the reason that, while it is difficult, if not impracticable, in many cases, clearly to define the boundaries between innocent and malignant formations, it is impossible to form any conception of such an occurrence. A tumor must be one thing or another, either innocent or malignant; it cannot be semiinnocent or semimalignant, although, as it respects portions of the same growth, one may be of this structure and another of that, as is occasionally witnessed in what is termed a combination tumor. A tumor may apparently be innocent so far as its autological phenomena are concerned, and yet be found, upon microscopic examination, to be malignant. A sarcoma is often as malignant as the worst form of carcinoma; and it must not be forgotten that a tumor originally benign may, in the course of time, assume the most destructive type.

Certain tumors, as, for example, the fatty, are composed chiefly, if not wholly, of a single tissue, and are hence designated as histoid. When the number of structures is greater, the term organoid is employed; while teratoid is the expression used when the formation is unusually complex, as when it represents the highest type of organization and development. The combination tumor, consisting of a union of several morbid growths, ingrafted, as it were, upon one another, is sufficiently common. Formations of an entirely different character, as the nævoid, cystic, fatty, fibrous, calcareous, and osseous, are thus occasionally associated in the same morbid mass, especially in the old, retrogressive forms.

The distinction between acute and chronic tumors is well founded. Most of the so-called innocent tumors are characterized by slowness of growth; now and then, however, a case is met with in which the development is very rapid, the morbid mass acquiring, perhaps in the course of a few months, a very extraordinary weight and bulk. To such a growth the term acute is applied, in contradistinction to the more ordinary chronic forms. Malignant tumors, as the different varieties of carcinoma and the worst types of sarcoma, generally possess a remarkable proliferating power, often advancing with frightful celerity.

The *etiology* of tumors is not well understood. That inflammation is frequently concerned in their production is unquestionable, a view which I have long entertained, and which is also held by Virchow, Samuel, Wagner, Birch-Hirschfeld, Cornil and Ranvier, Woodward, Formad, and others. In many cases, indeed, both of innocent and malignant tumors, their origin is directly traceable to the effects of injury, as a bruise or contusion. Keloid tumors often supervene upon burns, scalds, and other lesions; epithelial growths are very common at those parts of the skin and mucous membranes which are habitually exposed to irritation; and the influence of long-continued pressure in producing carcinoma is well exemplified in the undescended testicle compressed by the walls of the abdomen. In the great majority of cases, however, tumors of every descrip-

tion arise without any assignable cause. Examples of hereditary neoplastic formations are uncommon.

All forms of tumors occasionally manifest a disposition to return after extirpation, the secondary growths constituting what are called *recurrent tumors*. This tendency is not, as was formerly supposed, by any means peculiar to malignant growths, as the different varieties of carcinoma and sarcoma ; innocent tumors also occasionally exhibit it. With respect, however, to the latter, there is good reason to believe that recurrence is generally due to imperfect removal. Every surgeon has witnessed examples of recurrence after the excision of an ordinary sebaceous tumor of the face and scalp. The smallest fragment that is left behind in such a case must necessarily serve as the nucleus of a new growth, which may eventually attain the same bulk as the original. Proliferous cysts, chondromas, nævoid angeiomas, and myxomas, all, at times, manifest this disposition. In none of the morbid growths, however, is it so frequent, or so conspicuous, as in carcinoma and sarcoma, in the former of which it is always malignant, with a certainty of the early destruction of the patient, whereas, in the latter, the tumor may recur again and again, perhaps as often as three, five, or even six times, at intervals of several years, and death at last be produced by some other disease.

The recurrent growth may, in structure, be essentially like its predecessor, or it may exhibit typical variations ; not, however, so striking as to constitute material departures. The likeness to the parent still exists, at all events in certain parts, even when the new tumor assumes the character of malignancy. The new growth may appear at the site of the primary one, as, indeed, it most generally does, the cicatricial tissues seemingly serving as the starting-point. Not unfrequently, as in carcinoma, it selects the lymphatic glands. Occasionally an internal organ is involved, entirely unlike the original both in structure and function. Properly speaking, however, this is not a recurrence, consequent upon the removal of the primitive growth, for the same causes that may produce a tumor in one organ may produce a similar tumor in another, either simultaneously or consecutively. In strictness of language, the term recurrent should be limited to the new growth that occurs at the seat of the parent one. All other formations should be regarded as coincident or accidental, uninfluenced, so far as their exciting causes are concerned, by the one removed.

The secondary formations so often witnessed in the lymphatic glands, and in some of the internal organs, as the lung and liver, after the removal of carcinomatous and sarcomatous tumors, have their origin in cells that are detached from the original growth, and that wander about, as it were, in search of new homes, their transmission being effected by the lymphatic vessels, and probably, also, at least in many cases, by the veins. Such formations are now generally known by the somewhat equivocal name of metastatic tumors, and the state of the system, under the influence of which they are developed or generalized, as the infectious dyscrasia.

When a tumor that is originally innocent assumes a malignant character, the occurrence usually manifests itself by a rapid increase of bulk, by more or less serious encroachment upon the adjacent structures, especially the lymphatic glands, by a tendency to ulceration, by an impoverished condition of the blood, and by a constitutional dyscrasia, which becomes more and more conspicuous as the disease progresses.

Death from tumors may be occasioned by sheer malignancy, by the injurious effects exerted by the morbid growth upon important structures in its neighborhood, by secondary formations, by profuse hemorrhage, and by various other causes, as excessive suppuration, hectic irritation, pyemia, and erysipelas.

SECT. II.—CYSTS AND CYSTOMAS.

Cysts are sacs filled with more or less fluid contents. They may be classified in accordance with their mode of development, first, as retention cysts, or those which arise from the retention and accumulation of the normal secretion of glands ; secondly, as exudation cysts, or those which result from the distension of closed cavities ; thirdly, as dermoid cysts, or those which arise from fœtal inclusions ; fourthly, as cystomas, properly so called, or cysts of new formation, which are possibly due to cystic degeneration of the cells of the connective tissue ; fifthly, as extravasation cysts, or those which form around effused blood ; and sixthly, as hydatid cysts. It will be seen that I have excluded from this nomenclature the so-called softening cysts, which represent the fatty, mucous, and colloid degenerations of the tissues of the various neoplasms, thereby constituting the cystoid neoplasms. The proliferous cysts are also discarded, since, as for example, in the

mammary gland, they are merely solid projections of variously shaped masses into the deformed and enlarged ducts from the tissues which compose the original growth. As they are secondary changes, the neoplasms in which they are found are distinguished by the prefix cystic.

The cystic formations are not only of very frequent occurrence, but they are capable of acquiring an extraordinary bulk. Their contents, which are of a singularly diversified character, may be either solid, semisolid, or liquid. Occurring in nearly every organ and tissue of the body, they are particularly liable to arise in the skin and mucous membranes, the glandular organs, as the breast, testicle, liver, and the ovaries, and in the subcutaneous connective tissue. While no period of life is exempt from them, they are most common between the ages of twenty and forty-five, especially in females, who are also more subject to them than males, and in whom they frequently attain an enormous volume. Occasionally they have an intra-uterine origin, and in many cases they arise soon after birth.

1. RETENTION CYSTS.—Retention cysts consist merely of a thin cyst, sac, or bag, occupied by the natural secretion of the affected part, more or less altered by its protracted retention. An excellent type of this variety of morbid product is afforded by the so-called sebaceous tumor, which, in reality, is nothing more than a sebaceous follicle of the skin, in a state of hypertrophy from the occlusion of its orifice, and the consequent retention of the sebaceous matter. The immediate cause of the obstruction is inflammation, causing obliteration of the outlet of the follicle, and thus constituting the first link in the chain of morbid action. The second is the retention of the normal secretion of the follicle, which, being tightly pent up, undergoes important changes, both in its physical and chemical properties, leading to irritation, and sometimes even to inflammation of the sac, which, gradually enlarging before the accumulating and burdensome mass, at length forms a tumor perhaps as large as a medium-sized orange. The cystic tumor that is sometimes found upon the lower lip and upon the vulva arises in a similar manner. Ranula owes its origin to a like cause. Obstruction of a lactiferous duct may give rise to the cystic milk tumor of the breast. In the cysts which occur in the liver and kidney, the mode of formation is extremely simple, the hepatic and renal ducts being at first constricted, and finally, in many cases, obliterated by interstitial inflammation.

The contents of retention cysts must necessarily vary, as may be gathered from what precedes, according to the structure and functions of the affected part. Thus, in the mamma it contains milk, in the ranula saliva, and in a sebaceous formation sebaceous matter; altered, in every instance, in its physical and chemical properties. The cyst itself may be either solitary or multiple, and is generally composed of a single layer of connective tissue, its external surface, which is rough and flocculent, being more or less firmly adherent to the surrounding tissues, while the internal one, lined by epithelium, is usually smooth, shining, or glossy, without septa, and in immediate but loose contact with the proper contents of the tumor. It varies in thickness from the merest film up to that of a stratum several lines in depth. In cases of long standing it is occasionally partially converted into a substance resembling fibro-cartilage, cartilage, bone, or earthy matter.

Retention cysts are most appropriately described according to the nature of their contents, as serous, mucous, salivary, oily, milky, seminal, and sebaceous.

a. Serous cysts, the most common of all, are met with in all situations and at all periods of life, in their most simple as well as in their most complex form. Many of them are congenital, especially the more simple varieties, and not a few make their appearance soon after birth. Their most common seat is in the mammary gland, the liver, the kidney, the ovary, and the testicle.

The contents of these cysts are, as their name implies, generally of a thin, watery character, slightly saline in taste, and coagulable, in whole or in part, by heat and acids, thus showing that they are composed largely of albuminous material. The color is not always uniform. In the smaller and younger cysts the fluid is usually transparent, or clear and limpid, like well water; under opposite circumstances, on the contrary, it is often quite turbid, muddy, greenish, milky, or sanguinolent. In protracted jaundice I have occasionally found it to be of a pale lemon tint, evidently caused by the presence of bile; and in suppuration, to which, in certain situations, the cyst is very prone, the fluid is always intermixed with pus and lymph. The contents of certain serous cysts sometimes coagulate spontaneously on exposure to the air. Their walls are commonly thin, and originally translucent, if not actually transparent; but as they grow older they increase in thickness and density, and present an opaque appearance. Connective tissue, lined by

pavement epithelium, forms the essential basis of their structure, which, in cases of long standing, is often partially transformed into fibroid substance, with, here and there, perhaps, a minute calcified patch.

β. *Mucous cysts* occur chiefly in connection with the glands of the mucous membranes, those more particularly of the lips, the cheeks, the vulva, the vagina, and the uterus. Mucous cysts are occasionally developed in the maxillary sinus, in different portions of the alimentary canal, and in the glands situated in the posterior wall of the trachea, forming small projections between that tube and the œsophagus. They have also been observed in the larynx and upon the epiglottis.

The contents of mucous cysts are nearly always of a thick, ropy, glutinous consistence, intermixed with epithelial matter, and numerous corpuscles closely resembling white blood corpuscles. In the more recent cases the contents are thin and clear, like normal mucus or the white of an egg. Occasionally they bear a strong resemblance to the fluid of a synovial bursa; Paget has seen it of the color of the ink of the cuttle-fish; and in some cases, as those observed by Hawkins and Lebert, it has the aspect and consistence of thin fecal matter.

The cyst-wall is generally thin and composed of a single layer, smooth internally, lined by epithelium, and intimately adherent to the parts around by dense connective tissue. In shape, such tumors are usually spherical or pyriform, and in volume they range from a pea to a large fist or even a fœtal head, as is occasionally seen in the vulva and the vagina. Old mucous cysts of the genital organs are prone to inflammation and suppuration.

γ. *Salivary cysts* are peculiar to the salivary glands, being most frequent in the sublingual gland, constituting there what is known, surgically speaking, as ranula. A tumor of this kind, of considerable size, occasionally forms in the duct of Steno, from the occlusion of its orifice. The contents of these cysts are thick and ropy, like the white of egg, and consist essentially of saliva, mixed with a large quantity of mucous and epithelial matter.

δ. Cysts containing *milk*, sometimes of considerable bulk, are liable to form in the mammary gland during the process of lactation. At least half a dozen such cases have fallen under my observation, mostly in young females, within the first six or eight months after parturition. Obstruction of one or more of the lacteal ducts, from inflammatory deposits or inspissated milk, is the immediate cause of the formation. The size of the cyst is variable. In a case recorded by Scarpa, it was enormous, the contents amounting to upwards of one gallon. The fluid may be pure and perfectly liquid, or it may be combined with caseous and epithelial matter.

ε. *Oil cysts* are uncommon. They are usually quite small, and are generally due to advanced fatty degeneration of the epithelium of sebaceous cysts and of milk globules. Hence they are generally seated in the skin and breast. In one case, that of a young woman, I met with a cyst of this kind in the mammary gland partially filled with oil and a material strongly resembling curds, the result evidently of altered and disintegrated milk. The oil, on exposure to the air, sometimes congeals into a substance not unlike lard, containing acicular crystals of palmitine and stearine.

ζ. *Seminal cysts* are frequently confounded with hydrocele of the cord. The fluid from which they derive their name is chiefly composed of turbid serum, holding the characteristic spermatozoa, which can only be distinguished by the aid of the microscope, as it were, in suspension. Such bodies are occasionally contained in the fluid of ordinary hydroceles, but the only true spermatoceles, or seminal cysts, originate in dilatation of the seminal tubes in the vicinity of the head of the epididymis.

η. *Sebaceous cysts* comprise milium and comedones, which arise in the hair-follicles and contain epidermis; and steatoma or atheroma, which consists of an accumulation of sebum and epidermis in a sebaceous gland. As these formations are fully discussed among the tumors of the skin, their further consideration here need not detain us. A substance of a whitish pearly aspect is sometimes found in these cysts, described by some authors under the name of pearly tumor or cholesteatoma. The contents consist essentially of a white, dry, fatty substance, composed partly of epithelial cells and partly of cholesterine and palmitine and stearine, the whole being inclosed in a cyst of variable size and form. The growth, hitherto observed chiefly in the temporal bone, cerebellum, testicle, and ovary, is very uncommon.

II. *Exudation Cysts.*—Cysts which result from the accumulation of the contents of preëxisting closed cavities or cavities which are not provided with an excretory duct are known as exudation cysts. Among the most characteristic types of these formations are the *synovial cysts*, ordinarily known as ganglions and bursæ, which are so common in the

synovial sheaths of the tendons of the wrist and on the front of the patella, the latter constituting the so-called housemaid's knee. In the sheaths of the tendons and the natural burses the abnormal development is caused by the transformation of the cells inclosed in the fringe-like processes of the synovial membrane.

The volume of these cysts is generally small, and in their form they are, for the most part, rounded, globular, or hemispherical. In the sheaths of the tendons cysts of this kind have occasionally a tuberculated, knobby, or constricted appearance, as if they were divided, as, indeed, they not unfrequently are, into several compartments. The structure of the cyst-wall varies from simple connective tissue to fibroid, or even fibro-cartilaginous tissue, age and pressure being the principal modifying circumstances. Their contents may be serous, mucous, glutinous, colloid, or of jelly-like consistence, and of a whitish-opaque appearance. The so-called ganglionic cysts of the sheaths of the tendons, especially those of the wrist, often contain great numbers of small, free bodies, resembling cucumber seeds in shape, composed of compact connective tissue, and developed evidently under the influence of long-continued pressure and friction. Bursal cysts are very prone to inflame and suppurate; their walls are often very thick, and their inner surface occasionally exhibits a peculiar retiform appearance, the effect of inflammatory deposits.

III. *Dermoid Cysts.*—Cutaneous or dermoid cysts differ from sebaceous cysts in not being originally provided with an excretory duct, and in the composition of their walls, which contain all the elements of the cutis. They are always congenital, and are usually seated in the connective tissue around the orbit, root of the nose, floor of the mouth, near the angle of the jaw, along the sheath of the carotid vessels, in the vicinity of the anus, and in the sacrococcygeal region. In these situations, as well as in the anterior fontanelle, they evidently arise from the imperfect closure of the branchial clefts, and the clefts along the median line. Their contents are commonly composed of sebaceous matter and short, white hairs. In the ovary, the testicle, the brain and its meninges, the eye, the anterior mediastinum, the thymus, the lungs, the mesentery, and the omentum, in which they are also found, dermoid cysts may also contain teeth and rudimentary cartilage and bone, showing that they are probably the remains of fœtal inclusions.

IV. *Cystomas.*—Cysts of new formation, lined by endothelium, and containing serous contents, are of frequent occurrence, as is witnessed in the so-called congenital cystic hygroma of the neck, perineum, and axilla. Their mode of development is a matter of conjecture, but it is probable that they arise from cystic degeneration of the corpuscles of the connective tissue. A good example of the neoplastic cyst is the accidental burse which is developed under the influence of protracted pressure.

V. *Extravasation Cysts.*—Cysts occasionally form around extravasated blood, constituting what are known as hematomas or as sanguineous cysts. They have their seat most commonly in the neck, groin, and trunk. Their contents consist either of pure blood or of blood mingled with serum and other substances. The cyst-wall is usually very thin and smooth, but in some cases the inner surface has a peculiar fasciculated appearance, not unlike that of the right auricle of the heart. The cyst is commonly small, of a rounded or hemispherical shape, and fluctuates on pressure, especially in its earlier stages.

VI. *Hydatid Cysts.*—The hydatid cyst differs from the ordinary cyst in one essential particular, that is, it contains an entozoon, parasite, or vesicular worm, inclosed in a distinct, separate sac, originally described by Laennec under the name of acephalocyst, a term signifying headless bladder. The organs in which it is most commonly found are the liver, ovary, and uterus. It is also met with, although much less frequently, in the mamma, brain, testicle, kidneys, lungs, bones, serous cavities, and subcutaneous connective tissue. In my cabinet is a beautiful specimen of hydatid tumor which I removed from the deltoid muscle of a young man, a patient at the College Clinic.

Varying in volume between a mustard seed and a small orange, the entozoon is of a globular figure, of a whitish, semiopaque appearance, and composed of a vesicle, or bladder, filled with serous fluid, and surrounded by a fibrous capsule, which thus isolates and protects it from the circumjacent structures. It is usually gregarious, numbers of them inhabiting a common cyst, as in fig. 26; sometimes, however, there is only a solitary one, which is then commonly proportionately large. The contents of the animal are of a clear limpid character, remarkably saline to the taste, but destitute of odor and coagulability. The inclosing cyst is fibrous, more or less vascular, and possessed of considerable strength. Between this cyst and the parasite there is commonly a soft, pulpy, dirty-looking substance, the precise nature of which is undetermined. Owing to its endogenous

mode of generation, a large hydatid sometimes contains several smaller, one within another, like so many pill-boxes.

Although the hydatid itself consists of two distinct layers, it is generally so weak and delicate as to break under its own weight when removed from its inclosing cyst, shrinking into a soft, pulpy mass, not unlike the white of a hard-boiled egg, both in appearance and chemical composition. The inner surface of the parasite is studded with numerous little bodies, seen in fig. 27, resembling diminutive fish-spawn, hardly as large as a grain of sand, of a spherical shape, and of a grayish color, each consisting of a delicate cyst, filled with echinococci. The echinococci, deriving their origin and support from the hydatid, soon lose their connection, and thus acquire an independent existence, great numbers being often seen floating about in the parent liquor when they are yet hardly the two-hundreth part of an inch in diameter.

Fig. 26.

Hydatids inclosed in a common Cyst.

Each echinococcus consists of a body and a head, the latter being encircled by a row of teeth naturally concealed in a narrow cleft, but capable of projecting itself. The body, composed of solid, granular matter, has a curiously speckled appearance, due to the presence of numerous ovoid spots immediately beneath its outer coat. The teeth, or hooklets, are spinous, sharp, and perfectly characteristic. They are not easily decomposed, and are, therefore, capable of affording important diagnostic information. The various appearances here described are well illustrated in fig. 28.

Fig. 27.   Fig. 28.

Cysts of Echinococci.   Echinococci.

Hydatids are much less common in this country than in England and the continent of Europe. Nowhere, however, are they so prevalent as in Iceland, where, according to Eschricht, a sixth part of the population is infested with them. Men are more subject to them than women; and it is obvious that the ova of the parasite, derived for the most part from the dog, are introduced into the stomach with the food, from which they afterwards find their way into the different tissues and organs of the body. In one district, where the disease is most common, and where the inhabitants are accustomed to eat raw, smoked mutton, Dr. Hjaltelin reports that nearly every adult sheep and every third person are affected with the disease.

Hydatids are usually short-lived, rarely lasting beyond a few years. Various causes may destroy them, as suppuration, gangrene, the gradual desiccation of their contents, and the pressure of their young. Under such circumstances, the inclosing cyst is often remarkably thickened, and even partially transformed into fibrous, fibro-cartilaginous, or calcareous matter. I have seen instances where it had assumed an appearance similar to the interior of an aneurismal sac. Great mischief eventually arises from their presence, especially during their decay, from the violent irritation which they excite. A hydatid of the liver occasionally induces fatal peritonitis; and the hardest structures, the osseous not excepted, are not always capable of withstanding its progress. In one case a parasite of this kind perforated the scapula. In the lungs acephalocysts sometimes find their way

into the bronchial tubes, from which they are afterwards ejected by expectoration. In the kidneys they are commonly voided with the urine, either whole or piecemeal.

Under the term "multilocular echinococcus tumor," or "alveolar hydatid tumor," Virchow, Carrière, and other authors have described a form of this affection which differs from the ordinary variety of hydatid cyst, particularly in its structure. Instead of a cavity inclosing more or less rounded vesicles, it consists of a mass of solid tissue, strewed over with small, transparent bodies, resembling jelly. Scattered throughout the membrane are a great number of small cavities, or alveoli, which give it a worm-eaten or spongy appearance, and which vary in size from microscopic proportions to those of a hemp seed. They are filled with gelatinous bodies, which, on minute examination, are found to be composed of shrivelled hydatid membranes, echinococci, and hooklets. The tissue possesses a great tendency to ulcerate, as is evinced by one or more excavations of various sizes with ulcerated walls.

A very striking example of this form of tumor, the external appearances of which are delineated in fig. 29, came under my observation in 1869, in a German, fifty-four years of age, who had long been in the habit of eating pork.

Eight years previously, he noticed a swelling on the lower and inner side of the thigh, which, in a few weeks, attained the size of a fist, after which it remained stationary until four months before he consulted me, when it began to increase, and soon extended from the popliteal space to the pubes, occupying chiefly the inner aspect of the thigh, where it formed a soft, fluctuating tumor, from which I drew off thirty-five ounces of a dirty-brownish fluid, looking very much like ordinary yeast. One month subsequently, I laid it open by an incision twelve inches long, and dissected away the exterior adventitious sac or lining membrane. It contained many cysts, each invested by an adventitious membrane, and occupied by pus, the largest being about the size of a goose-egg. The adventitious sac was subcutaneous, two lines in thickness, and studded with small gelatinous bodies and alveoli, the former of which presented all the characteristics of ordinary hydatid membrane, and the parasite with its hooklets. The fluid in the adventitious cyst consisted of pus in a state of advanced fatty degeneration.

There are no signs by which a hydatid tumor can be satisfactorily diagnosticated. The only positive evidence of its existence, when it is seated in an internal organ, is the presence of the vesicle, or of some of its constituents, in the discharges, as the urine, sputa, or feces. It is not often that an acephalocyst is voided entire; most generally it comes away in broken pieces, or in shrivelled fragments, consisting

Fig. 29.

Hydatid Tumor of the Thigh.

of hooklets, laminated shreds, milky-looking detritus, and oily particles, discoverable with the microscope. When the tumor is situated superficially, or when it is developed among muscles, in a broad bone, the liver, kidney, or mammary gland, it fluctuates more or less distinctly on pressure, and yields the peculiar characteristic thrill, known as the hydatid fremitus. In order to elicit this sign, the fingers of one hand should be laid upon the tumor, and tapped sharply with the fingers of the other. The sensation thus communicated has been compared by Davaine to the vibrations of a repeater watch held in the hand. In some cases it closely resembles the peculiar crepitating feel produced by pressure applied to a burse of the knee or to a ganglion of the hand. A similar sensation is communicated to the ear when the stethoscope is used, and the tumor is percussed with the fingers. Not unfrequently all attempts, however patiently or skilfully conducted, utterly fail in throwing any satisfactory light upon the nature of the affection.

The diseases with which hydatid tumors are most liable to be confounded are abscesses, especially the strumous variety, hypertrophy of the liver and spleen, accumulations of bile in the gall-bladder and of fecal matter in the large bowel, aneurism of the aorta, en-

largement of the ovary and uterus, and various kinds of tumors of the abdominal and pelvic viscera, particularly the cystic, fibrous, and carcinomatous.

Treatment.—Cysts are never benefited by constitutional medication, except in so far as it may have a tendency to improve the general health, and thus retard their development. Their contents do not seem to be amenable to the action of the absorbents. When they are situated superficially and are of small size, their growth is sometimes retarded, although they are seldom cured, by compression, and by sorbefacient applications, particularly the dilute tincture of iodine. A more certain plan is to break the cysts or incise them subcutaneously, so that, their contents having escaped into the surrounding connective tissue, their walls may collapse, and ultimately unite by adhesive inflammation. When the tumor is deep-seated, iodine injections may sometimes be advantageously employed, the operation being performed in the same manner as in hydrocele of the vaginal tunic of the testicle. A seton, too, is an eligible procedure. When the cysts are large or numerous, and, above all, when the primitive textures are, in a great measure, if not entirely annihilated, the only course likely to succeed is excision of the entire mass, care being taken not to leave the slightest particle, for fear of reproduction. Too much stress cannot be laid upon this injunction. For want of this precaution, I have known a patient to be obliged to submit to not less than three distinct operations for the cure of a tumor originally not larger than a pigeon's egg. A secreting surface, hardly the size of a pin's head, is capable of reawakening growth. Removal may sometimes be effected by enucleation; at other times, and more generally, a minute dissection is necessary. The proceeding need not be at all bloody, unless the tumor is seated among very vascular parts, or the knife is carried too far away from the encysted mass.

The treatment of hydatid cysts varies according to their site. When the tumor is situated externally, as, for example, when it occupies the mammary gland, a muscle, or a bone, the only remedy is excision. When, on the contrary, it occupies an internal organ, as the liver or kidney, the proper plan is to evacuate its contents with the trocar, and provoke obliterative inflammation by the injection of a weak solution of iodine or the insertion of a tent. When no contraindication exists, a free incision may sometimes be advantageously made. Electrolysis has occasionally been successfully practised. The treatment is especially adapted to hydatids of the breast and liver. When the hydatids infest the kidney, the best internal remedies are oil of turpentine and nitrate of potassium, in moderate doses, repeated several times in the twenty-four hours.

SECT. III.—NEOPLASMS WHICH REPRESENT PERFECTED OR MATURED CONNECTIVE TISSUE AND ITS MODIFICATIONS.

1. LIPOMATOUS TUMORS.

The lipomatous or fatty tumor is not only very common, but may occur in any part of the body, not even excepting the hand, foot, fingers, and toes. It is seen, however, more frequently about the nucha, back, shoulder, and arm than in any other regions. The upper eyelid is also a common seat of it. Sometimes, but more rarely, it is developed in the orbit of the eye, the walls of the abdomen, perineum, labium, and underneath and even in the substance of the tongue. Recently I removed a small tumor of this kind from the forehead of a woman, forty-three years of age; and on another occasion one, the size of an orange, from the left temple of a man of thirty-five. Dr. Hatfield, also, met with an adipose tumor on the forehead, and Dr. S. W. Gross removed one in a middle-aged person from the occipital region. Large masses of fat occasionally form in the internal cavities of the body, as in the omentum and mesentery, and around the kidneys.

The number of fatty tumors varies, in different cases, from one to several hundred. In general, they are solitary, or, at most, there are only two or three, occupying different regions of the body, or grouped more or less closely together. In a physician, a former member of my class, thirty-eight years of age, I counted upwards of two hundred, from the volume of a small pea to that of a large marble. They all had a doughy, inelastic feel, and most of them were of a globular shape, a few being slightly flattened or compressed. They were situated principally on the forearms, inside of the thighs, loins, abdomen, and pectoral regions, the latter of which were literally covered with them. None existed on the head, neck, and upper part of the back. The general health was good, and the tumors had been first observed about sixteen years previously. During two severe attacks of acute disease, accompanied with great emaciation, many of them

entirely disappeared. The late Dr. Nott, of New York, mentioned to me the particulars of a similar case.

In their volume, these growths range from a small pea to that of an adult head. Sometimes, indeed, they are much larger, measuring many inches in diameter, and projecting a great distance beyond the surface. I am indebted to Professor Leidy for a section of a fatty tumor which weighed upwards of seventy pounds; it was removed, after death, from the abdomen of an elderly person, and contained large masses of bony matter. Dr. Bray, of Evansville, Indiana, extirpated a growth of this kind which weighed nearly forty pounds, the patient making a good recovery.

In their form, fatty tumors are generally somewhat globular, with a lobulated surface, as in fig. 30, from a specimen in my collection; as they augment in volume, however, they are liable to become elongated, and to assume a pyriform, gourd-like, or pedunculated configuration. These changes, no doubt, depend upon their weight, by which they are gradually dragged out of their original shape, as well as position. For the same reason they sometimes shift their seat, descending from the point where they originally appeared to one below it, perhaps several inches distant. Thus, a fatty tumor developed in the groin has been known, in time, to pass down between the scrotum and the thigh. This migratory tendency, which is of special interest in a diagnostic point of view, is most common in those parts of the body which are most abundantly supplied with loose connective tissue, and in those cases in which the tumor has a large bulk and a pedunculated attachment. Occasionally their edges, have a dentated arrangement, due to subordinate outgrowths of variable size and forms.

The fatty growth is always surrounded by a fibrous capsule, by which it is connected more or less firmly to the parts around, the strength of the adhesions being generally in

Fig. 30.

Lipomatous Tumor.

proportion to the age and bulk of the tumor, and the amount of pressure exerted upon it during its development. Attached to the inner surface of this covering are numerous processes, which, dipping into the interior of the growth, separate it into lobes, lobules, and granules, until the component tissues are resolved into their ultimate elements. These processes, which are usually very delicate, are occasionally, as when there is a hypertrophic condition of the connective tissue partitions, very dense and tough, forming distinct bands, of a whitish or grayish color, between the different structures.

When a fatty tumor contains an unusual quantity of fibrous matter, as when its capsule and intersecting processes are very thick and dense, it constitutes that form of morbid growth to which Müller, Rokitansky, Gluge, and other German histologists, have applied the terms mixed lipoma, steatoma, and lardaceous tumor. The name fibro-fatty would be more appropriate, although the distinction is of no practical value.

A growth in which the adipose element is intimately combined with the vascular, although not in an equal degree, is sometimes met with, chiefly upon the back, thigh, and buttock, and is known as the nævoid lipoma. It has a soft, doughy, inelastic feel, is free from pulsation, pursues a slow, indolent course, is generally congenital, is essentially composed of a cellulo-adipose basis, interspersed with enlarged veins, and occasionally manifests a recurring tendency after extirpation.

Fatty growths generally receive very little blood, and they therefore seldom bleed much when they are extirpated. It is only when they are of large size, or of very rapid development, that they are likely to be very vascular. The capsule and its processes serve to conduct the vessels into the interior of the morbid mass, and to direct, as it were, the distribution of their branches and ramifications. As the tumor is always free from pain, and tolerant of the rudest manipulation, it may be concluded that it does not receive many nerves. Absorbent vessels also exist sparingly. It may, furthermore, be inferred that, as the general health

Fig. 31.
Minute Structure of a Fatty Tumor.

is usually unimpaired throughout the whole progress of the affection, however protracted, it does not possess any important sympathetic relations with the general economy.

The minute structure of this form of tumor is well displayed in fig. 31. It is made up of cells, exactly similar to, but larger than, those of natural fat, interspersed through connective tissue, as seen in the larger drawing: the small figure *a* represents isolated cells, showing the crystalline nucleus of margaric acid. Various other substances, of an adventitious character, are generally perceived under the microscope, more especially in the older growths.

The fatty tumor often sends prolongations around the muscles, tendons, fasciæ, vessels, and other structures. Thus in the neck it occasionally extends deeply between the trachea and œsophagus, dips in between the carotid artery and jugular vein, or passes down behind the sternum and clavicle into the chest. A fatty growth of the wall of the abdomen is sometimes prolonged into its cavity; and, on the other hand, such a tumor occasionally begins in the subperitoneal connective tissue, and ultimately descends through the inguinal canal, or through some abnormal outlet, down into the scrotum, thus simulating hernia of the groin. All such arrangements must necessarily greatly embarrass both the diagnosis and the attempts to remove the morbid mass.

Fatty tumors are generally easily recognized by their soft, doughy, semielastic feel, their mobility, their well-defined outline, their uniform consistence, their lobulated surface, their tardy progress, and their indolent disposition. Some are pedunculated, some pendulous, some pyriform, or gourd-like, some flattened, as if compressed, and some ramiform, processes extending in different directions among the muscles, vessels, and other structures. There is no pain, no tenderness on pressure, no impairment of the health, no enlargement of the subcutaneous veins, and no inconvenience, except what is occasioned by the situation, bulk, and weight of the growth.

Inflammation, suppuration, ulceration, and even gangrene may occur in these growths, usually induced by mechanical pressure, caustic applications, or inefficient nourishment, in consequence of a loss of their vascular and nervous supply from the pendulous or overgrown character of the morbid mass. In a tumor of this kind, about the volume of an orange, which I removed from the top of the left shoulder of a girl eighteen years of age, the ulcer had a remarkably foul, unhealthy aspect, with thin, everted edges; the pain was, at times, very severe, and the discharge was of a sanious nature, intermixed with globules of fat. Various attempts had been made, but without success, to heal it up, and no cause could be assigned for its formation. The general health had been a good deal impaired, and there had latterly been some irregularity of the menstrual function. The ulcer was included in two incisions, and speedy recovery was the result.

Again, such tumors now and then undergo the fibrous, cartilaginous, calcareous, or osseous degeneration, not uniformly, but at certain points of their extent. Nodules, varying in size from a hazel-nut to a pullet's egg, may thus be formed, having a firm, characteristic consistence, more or less movable, and contrasting singularly with the other structures. Finally, they occasionally contain cysts filled with various kinds of substances, as oily, serous, mucous, or gelatinous. The walls of the cysts may be very thin and transparent, or thick, opaque, and perhaps even partially calcified.

Fatty growths generally arise without any assignable cause. Sometimes, though very rarely, their development is apparently due to external injury, as a blow, contusion, or persistent mechanical compression. It is most common in young adults and middle-aged persons. Occasionally it is congenital, as in the interesting cases reported by Johnson, Gay, and others.

The medical treatment of this class of morbid growths is most unsatisfactory, as there is no remedy which seems to be capable of arresting their progress, or of causing their removal. The instance of Sir Benjamin C. Brodie, in which he succeeded in dispersing a large mass of fat from a man's chin and neck, by the free and persistent use of the officinal solution of potassa, may be regarded as a remarkable example of good luck. All local means, as systematic compression, and sorbefacient lotions, liniments, and unguents, are equally useless, the absorbent vessels being seemingly incapable of responding to their action.

The manner of excising such tumors is generally sufficiently simple. Any diseased skin that may exist should be removed along with the morbid mass, which should be enucleated

by a rapid dissection, care being taken that not a particle of the tissue is left behind; otherwise reproduction may take place. When the tumor is superficial, the operation is easily performed and soon over; but when it is deep-seated, or when it sends processes among the surrounding structures, it may be one of great difficulty and perplexity, requiring consummate skill and a most thorough knowledge of the anatomy of the parts. A fatty tumor that has long been compressed, as when it occupies the nape of the neck, shoulder, or buttock, is often removed with difficulty, owing to its firm and extensive adhesions. For the reasons already mentioned, the operation is sometimes nearly bloodless. I have, indeed, seldom found it necessary to apply more than two or three ligatures, whatever may have been the volume of the tumor.

When a fatty tumor is completely extirpated, there can be no recurrence of it. In a case of lipoma of the scrotum, recorded by Mr. Curling, in which there was a reproduction five times, the new product was evidently merely an outgrowth of a part of the pedicle which in each instance had been left behind.

2. FIBROUS TUMORS.

The fibrous tumor owes its name to its peculiar structure, which strongly resembles normal fibrous tissue. One of the best examples of this variety of morbid growth is to be found in the uterus of elderly females, where it sometimes attains a weight and magnitude equal to those of the body of the patient. It also occurs in the connective tissue, both subcutaneous and intermuscular, in the mammary gland, testicle, ovary, periosteum, bones, nerves, and other parts of the body. In my cabinet is a large fibrous tumor, weighing nearly five pounds, which I removed from the interior of the scrotum of a young man of twenty-five, but which had no connection whatever with the testicle. A remarkable fibrous tumor sometimes grows pendulously from the lobe of the ear. Certain keloid formations of the skin obviously belong to the present class of morbid products, although they usually contain an inordinate quantity of fibroplastic tissue. Fibrous growths occasionally occur in the interior of the joints, especially the elbow and knee, in the latter of which they sometimes attain the volume of a pullet's egg. The dura mater, periosteum, and fibrous envelop of the muscles are all liable to such formations, although the occurrence is unusual. Finally, fibrous tumors are often met with in the neck, either immediately beneath the skin or deep among the muscles and lymphatic glands. Not long ago I removed from a lady, forty-three years of age, a small nodule of this kind from the site of the lachrymal sac, which was almost completely obliterated by its pressure. Certain polyps, as they are called, are of a purely fibrous structure.

This growth is not peculiar to any period of life. The greatest number of cases, perhaps, occur in young adults. In the uterus and ovary it is most common in elderly subjects. It is sometimes congenital, and I have met with it also in several members of the same family.

The fibrous tumor, although of slow growth, may eventually acquire an enormous bulk, as is exemplified in the immense masses which are occasionally found in the neck, the uterus, and other parts of the body. It feels heavy and incompressible, is globular, ovoidal, or pyriform in shape, and has generally a smooth, even surface, although not unfrequently it is remarkably lobulated, or marked by numerous elevations and depressions. In the uterus and the joints it is often attached by a narrow neck, while almost everywhere else it is in immediate contact, on all sides, with the structures in which it is developed, its adhesions being effected by connective tissue. Generally solitary, it occasionally occurs in considerable numbers, more particularly in the uterus, which is sometimes completely crammed with it. In the case of a woman, sixty-six years old, Lebert found several hundred fibrous tumors scattered through the subcutaneous connective tissue in different parts of the body. In the nerves upwards of one thousand have been observed in the same person.

The structure of this tumor is characteristic. As its name indicates, it is composed of fibrous tissue, the filaments of which cross each other in every conceivable manner, forming thus an intricate network, which the most careful dissection fails to unravel. These filaments are of variable size and shape, and are so intimately compacted together in the firm variety as to form a dense, hard, inelastic substance, so characteristic of this kind of product. It is only in rare cases that their passage across each other leaves any interspaces for the lodgment of fluid or solid matter. They are of a grayish or pale drab color after maceration, but in their natural state rosaceous, reddish, or even purple, their complexion depending upon the amount of blood they contain. Occasionally they have a

whitish, silvery, glistening appearance, like the sclerotic coat of the eye. The soft variety, as, for example, the molluscous fibroma, possesses a looser and a less dense texture, resembling that of the subcutaneous connective tissue, and its color is usually white, reddish, or yellowish.

The fibrous tumor has seldom any distinct capsule ; the tissues around it are, it is true, usually a good deal condensed and thickened, but the covering thus derived is altogether adventitious and secondary, forming none of the essential elements of its growth. Few vessels can be traced into its substance, and these are rarely of any considerable size ; a circumstance the more surprising when it is recollected what immense bulk it sometimes acquires. No reliable chemical examination has been made of this variety of tumor, but it is probable that it consists essentially of gelatine, as this substance is largely furnished by protracted boiling. Under the microscope it exhibits hypertrophied fibres, between

Fig. 32.
Microscopical Characters of Fibrous Tumor from the Submaxillary Region. ×472 Diameters.

which are interspersed, sometimes in great numbers, small ovoidal or fusiform cells, containing bright nuclei, which are always rendered very conspicuous if the part be previously treated with acetic acid, as in fig. 32, from a drawing of one of my specimens by Dr. Packard.

A fibroma sometimes contains mucus, the result of softening, lodged in distinct cells or cavities, and giving rise to a mixed form of tumor, known as the myxomatous fibroma. The presence of the mucus probably serves to give additional impulse to the development of the tumor, which occasionally increases with remarkable rapidity, and soon acquires a large bulk in consequence.

The general tendency of the fibrous tumor is gradually to increase, to impair function, and ultimately to wear out life by its secondary effects. The older formations of this kind nearly always contain adventitious deposits, especially the calcareous, which often exist in considerable quantity. The cartilaginous is also not uncommon, while the osseous is rare. Sometimes large cavities, containing serum, pus, and other substances, are found in them. In a case observed by Paget, a fibrous tumor of the uterus contained a mass of fat the size of a large walnut.

Their progress is usually painless, except when they compress important parts, the inconvenience which they occasion being dependent mainly upon their weight, bulk, and site.

A growth of this kind sometimes takes on malignant action, its tissues serving as a nidus for sarcoma. Although it is impossible to determine what are the circumstances which predispose to, or influence, such an occurrence, there can be no doubt that it is governed by the same laws as those which preside over the development of sarcoma in the connective tissue generally, and that the change does not consist in a degeneration, properly so termed, of the fibrous substance, but in an entirely new formation. The neoplasms, which were described in former editions as fibroplastic and recurring fibroid tumors, will be discussed in the section on sarcoma.

The diagnosis of the fibrous tumor must mainly be deduced from its history and its consistence. Its growth is generally very tardy, there being a marked difference, in this respect, between it and the carcinomatous formations. Usually beginning in a little hard nodule, or lump, several years commonly elapse before it attains any considerable bulk, especially when it is developed among the external tissues ; its progress is comparatively painless, the chief inconvenience occasioned by it being of a mechanical nature. The tumor usually feels hard, firm, and inelastic, being more dense than encephaloid, but not so solid and dense as scirrhus. Its consistence is usually uniform ; not hard at one point and soft at another. Its surface, too, is commonly smooth ; and there is nearly always, unless the growth is very large, an absence of enlargement of the subcutaneous veins. In its earlier stages it is somewhat movable, except when it springs from the periosteum ; by degrees, however, it contracts adhesions, and is thus firmly fixed in its position.

The fibrous tumor is rarely amenable to local or constitutional treatment. When favorably situated, pressure, steadily and systematically applied, is sometimes serviceable : but this is so seldom the case that hardly any calculations of a curative character are to be based upon it. In the early stage of the development, before any great firmness and density of structure are attained, a mild course of mercury may be tried, its constitutional impression being persistently but very gently maintained for several successive months, or alternated with that of iodide of potassium, also an agent of some consequence in the

softer forms of fibrous growths, although rarely of any benefit in those of maturer development. But the surest remedy, when the tumor is accessible, is removal, performed early and efficiently, by dissection and enucleation. Hemorrhage is usually slight, and recurrence not probable, unless, as sometimes happens, the morbid mass has become the nidus of sarcomatous deposit. As this cannot always be certainly predicted, the prognosis should not be too sanguine.

3. CARTILAGINOUS TUMORS.

The cartilaginous tumor, first accurately described by Professor J. Müller, under the name of enchondroma, or chondroma, holds, histologically, a position intermediate between the fibrous and osseous, and is harder than the former and softer than the latter. It is divided by Virchow, primarily, into ecchondroses, which spring from the permanent cartilages, and enchondromas, which are developed from a non-cartilaginous basis. The former, which do not differ from the latter in their clinical history and minute structure, have a predilection for the costal, pelvic, laryngeal, and tracheal cartilages, and they also form the movable bodies of the articulations.

Enchondroma occurs in various parts of the body, as the parotid and submaxillary glands, the testicle, and ovary, as well as in the subcutaneous and intermuscular connective tissue, but is most frequent in the skeleton, as the metacarpal bones and the phalanges of the fingers, where it may be central or periosteal. I have seen large and numerous growths of this kind form simultaneously upon both hands and both feet, causing hideous deformity and almost complete loss of function of the affected parts. The most formidable tumors of this kind are generally met with in the scapula. Although they occasionally occur in elderly subjects, they are by far most common in young persons before the twentieth year, especially in such as are of a weak, rickety constitution; and they are often associated with a remarkably stunted state of the body. The annexed sketch, fig. 33, from a specimen in my possession, conveys a good idea of the external characters of an enchondroma of a finger.

The enormous size which a cartilaginous tumor is capable of attaining is well illustrated in a case which came under my observation in a young man, twenty-six years of age. The tumor, which occupied the right shoulder, had appeared about six years previously, and involved the scapula, humerus, and clavicle, forming an immense mass, of very irregular outline, excessively hard, forty-five

Fig. 33.

Enchondromatous Tumor.

inches in circumference at the base, and weighing, after death, as was ascertained by Dr. H. J. Bigelow, thirty-one pounds. In another instance, one which I saw with Dr. Davison, of Illinois, in a man forty-five years of age, an enormous mass of this kind, having its origin in the scapula, and occupying the left side of the trunk, weighed ninety pounds. In a case of enchondroma of the femur, related by Sir Philip Crampton, the tumor measured six feet and a half in circumference. Mr. Gamgee, in 1862, amputated successfully at the hip-joint, in a case in which a growth of this kind, along with the thighbone, weighed ninety-nine pounds.

The structure of enchondroma corresponds with the type of permanent cartilage, consisting either of hyaline, fibrous, or reticular tissue alone, or, as is nearly always the case, of all those varieties variously intermingled, so that, in reality, most tumors of this kind are of a mixed character. Portions of it undergo different transformations, and in cases of long standing, or of extraordinary bulk, mucous, fatty, fibrous, cartilaginous, calcareous, osseous, and sarcomatous changes are almost always met with. It also not unfrequently contains large cysts filled with various kinds of substances, either solid or fluid. To the hand it imparts the sensation of unusual firmness and solidity; it is destitute of elasticity, is generally distinctly circumscribed, and is nearly always strongly adherent to the tissues from which it springs. Its surface, which is sometimes smooth, is commonly lobulated, or marked by irregular prominences and depressions. No pain usually exists, or, if there be any, it is owing rather to the pressure which the tumor exerts upon the neighboring parts than to any disorder of its own sensibility. When the growth is very old and bulky, there is generally great enlargement of the subcutaneous veins, with a tendency to softening and disintegration of its more feebly organized portions.
The cartilaginous tumor varies in consistence, not only in the different stages of its life, but in different portions of its extent. The older sections are generally hard, firm, dense, cutting with difficulty, and creaking under the knife; the younger, on the contrary, are soft, almost gum-like, or of the consistence of honey, warm glue, isinglass, or synovia. Sometimes almost the entire tumor is semiliquid; at other times the fluid matter is contained in distinct cysts or cavities, and in some cases, again, the fluid parts are intermixed with fibrous, cartilaginous, or osseous nodules. The softer portions may be present as an original product, or they may be the result of secondary formation, consequent upon deficient nutrition, or retrograde, degenerative changes. On section, it is of a whitish, grayish, or bluish aspect, and is characterized by a peculiar linear or lobular arrangement.
Fig. 34.

Microscopical Characters of Enchondroma.

Under the microscope this tumor presents numerous cells, as in fig. 34, of an oval or rounded shape, from the $\frac{1}{700}$ to the $\frac{1}{1500}$ of an inch in diameter, provided with one or two nucleolated nuceli, and lodged in cavities of various sizes and forms, distributed through an amorphous hyaline, mucous, dimly fibrilliated, or coarsely fibrous, intercellular substance. In the older growths, some of the cells are cloudy and shrivelled, others are in a state of fatty degeneration, while others, again, are marked by projections similar to those of cartilage in process of ossification. Its principal constituent is chondrin in union with phosphate of lime. The animal matter, readily extracted by boiling, solidifies on cooling like gelatine, but does not contain any of the latter substance, as is shown by the fact that it does not expand by contact with fluids.

The cartilaginous tumor is sometimes inclosed by a distinct cyst of condensed connective tissue; at other times it is in immediate contact with the structures in which it is developed. Its vascularity is often very great, a circumstance which readily explains the astonishing rapidity which occasionally marks its progress, cases having been observed in which, in the course of a few months, the tumor attained the size of an adult's head, or even of the patient's chest. Such an occurrence, however, is extremely uncommon; for the development of enchondroma is usually singularly tardy, and now and then, it apparently enjoys even a period of repose.

Enchondroma is generally painless and indolent, causing little or no inconvenience, save what results from its weight and pressure; sometimes, however, it inflames and ulcerates, and in this way a large cavity may be formed, attended with copious discharge and excessive constitutional disturbance, rapidly followed by hectic fever. Portions of it may, as already stated, undergo various transformations, as the cystic, fatty, fibrous, calcareous, and osseous; and segments occasionally degenerate into malignant disease, nodules of cartilage, of various shapes and sizes, being interspersed through the sarcomatous tissue, each invested by connective tissue.

Although the cartilaginous tumour is generally an innocent growth, it sometimes assumes a malignant form, and numerous instances have been reported in which it recurred after extirpation, not only once but repeatedly. The recurring tendency is well exemplified in the remarkable case observed by the late Dr. Reuben D. Mussey, in which the disease successively invaded the hand, arm, and shoulder, the second operation being performed thirteen years after the first, and the last, in which the entire scapula and clavicle were successfully removed, five years after the second. Syme performed amputation at the shoulder-joint, in a girl, fourteen years of age, on account of a cartilaginous tumor which reappeared in the stump and in the axilla. In two cases, recorded by Gluge, the disease returned and destroyed life, respectively, at eighteen months and two years and a half. Virchow relates an instance in which an enchondroma of the scapula recurred seven times, and finally proved fatal. Under such circumstances similar growths are frequently found in other organs, as the lungs, liver, spleen, and testicle. The extension of cartilaginous tumors, by the lymphatic vessels, has been repeatedly observed, the vessels being remarkably tortuous and dilated, and filled with cartilaginous matter. It is not, however, at all certain that in the recorded cases of malignity of enchrondroma the tumor was constituted by cartilage alone; and I am of the opinion that the cartilaginous tumor never occasions secondary deposits, unless it is combined with sarcoma, myxoma, or carcinoma.

The only remedy for this tumor is early and efficient extirpation. The operation,

however, as already stated, is not always successful, for now and then repullulation occurs, either causing death, or demanding further surgical interference. This is especially liable to happen when the tumor sends out small processes into the surrounding structures, or is not distinctly incapsulated, and when sarcomatous elements are intermingled with the cartilaginous. When the new growth is closely connected with bone, amputation will always be required.

4. OSSEOUS TUMORS.

Osseous tumors, or osteomas, usually known as exostoses, are met with chiefly as outgrowths of the skeleton, especially of the skull and thigh-bone, the superior jaw, the orbit of the eye, and the distal phalanx of the big toe, occurring in various forms and sizes, from a pea up to a fœtal head; hard and compact, like normal bone, which they closely resemble in structure and composition; slow and painless in their progress; seldom, if ever, degenerating into malignancy; unamenable to ordinary medication; and demanding removal only when they seriously interfere with the exercise of important functions. Osteomas, not directly connected with bone, or continuous with bone, occasionally occur as the result of ossification of the cartilaginous, muscular, tendinous, and aponeurotic tissues, but their consideration does not properly belong to the present subject; and a similar remark is applicable to those peculiar osseous formations which are sometimes met with as isolated bodies, of varying forms and sizes, in the substance of different organs, as the brain, lung, ovary and testicle, and in connection with different kinds of soft tumors. A well-marked exostosis, constituting what is called an odontoma, occasionally forms on the root of a tooth, especially of the large grinders.

Osseous tumors, properly so called, are, in reference to their structure and mode of growth, divisible into two classes, the soft, spongy, or cancellous, and the compact, hard, or ivory-like. The former, which is by far the more common, has usually a cartilaginous origin, and is often, especially in its earlier stages, invested by a layer of this substance, from one to several lines in thickness, of a grayish, whitish, slightly bluish, or pearly aspect, and of a hyaline character. Sometimes it is inclosed by a thin fibrous capsule, a form of synovial burse, lubricated by serous or sero-oleaginous fluid. Such an arrangement is most common in osteomas near the larger joints, in connection with the epiphyses of the long bones, and is evidently designed to facilitate the movements of the soft parts immediately around the morbid growth.

In its shape the cancellous osteoma is generally more or less rounded, with a nodulated surface, and a broad base; occasionally it is very irregular, spiculated, or angular; and now and then it has a distinctly pedunculated form. It is of a dense, firm, bony consistence, and is only movable while it retains its fibrous, periosteal, or cartilaginous attachment. Its volume usually ranges between a pea and an adult fist, although it is capable of acquiring much larger dimensions. The structure and chemical composition are as nearly as possible like those of normal bone, both in its compact and medullary substances. Cancellous osteomas sometimes arise in the medullary canal and within the frontal sinus, forming thus what, in strictness of language, may be called enostoses, which, however, in no wise differ in structure and composition from exostoses, or external bony outgrowths. The most frequent seats of the cancellous exostosis are the femur, tibia, fibula, and humerus.

The ivory-like tumor is destitute of cancellous substance, and is so firm and dense as to be severed with great difficulty, the section admitting of a fine polish, very much like the substance to which it owes its name. Phosphate and carbonate of lime are present in unusual quantity, although it is not improbable that its hardness depends more upon the mode of aggregation of its several constituents than on chemical differences. The Haversian canals and lamellar arrangement are always well marked. Of a rounded, globular, or hemispherical shape, the morbid growth is generally smooth, or slightly nodulated, of small size, and attached by a narrow base, often of a cartilaginous character. Its most common site is the skull, and it may grow either from the outer or the inner table; more generally the former.

Osteomas are generally of slow growth, and the principle inconvenience occasioned by them arises from their situation, bulk, weight, and pressure. Severe pain, mostly of a dull, heavy, aching character, may be produced by them when they overly, inclose, or compress important nerves. The general health is usually unaffected. The diagnosis is easily established by the history of the case, and by the firmness, density, and immobility of the tumor, which are greater than those of any other morbid growth. The cau-

cellous osteoma is most common in young subjects, before the twenty-fifth year; the ivory-like in advanced age. Of the nature of their exciting causes nothing definite is known. Their origin, in many cases, is directly traceable to external injury; and instances occur in which there is a veritable exostotic diathesis, exostoses, sometimes of a symmetrical character, existing, perhaps, upon almost every bone in the body. A hereditary tendency to these outgrowths is occasionally witnessed; and I have met with examples of them in several members of the same family.

It is possible, I presume, for an osteoma, under the influence of injury, protracted pressure, and general ill-health, to assume malignancy; but such an event is extremely uncommon. The occurrence of caries and necrosis is also very infrequent. A sponta-neous cure sometimes takes place, the growth, from the interruption of its circulation, losing its vitality, and finally dropping off as an extraneous substance. Such an event is most common in osteomas of the head and face. Medication is of no avail in arresting the progress of the disease, except when the tumor is very small and young, when sorbe-facient applications, judiciously employed, are occasionally of use. As long as the growths cause no serious inconvenience they should not be subjected to operative interference, as the patient might perish from erysipelas, pyemia, or profuse suppuration. The bursal covering of an exostosis seated on the epiphyses of the long bones sometimes opens into a neighboring joint, rendering such interference doubly perilous.

5. LYMPHOMATOUS TUMORS.

A lymphoma is a neoplasm composed of a tissue similar to that of the follicles of the lymphatic glands, or the adenoid tissue of His, which, as is now well known, is widely distributed throughout the body, being found not only in the lymphatic glands, but in the parenchyma of the various organs, the medulla of the bones, the tonsils, the pharynx, and the mucous membrane of the intestinal tract. In France the growth is called lym-phadenoma; but as that term is also applied to the affection which in England is styled Hodgkin's disease, it should be discarded. By other writers the term lymphosarcoma is loosely employed as the equivalent of lymphoma, which is altogether improper, as the two affections differ widely from each other in their minute structure and in their clinical features. In the following description the term lymphoma will be employed as signifying progressive hyperplasia of preëxisting lymphatic tissue, and has, therefore, nothing in common with sarcoma, or the enlargements due to ordinary inflammation, struma, syphilis, tubercle, Hodgkin's disease, or lymphatic leukæmia.

Fig. 35.

Minute Structure of Lymphoma.

Viewed in the sense here indicated, the lymphomatous tumor is most frequently met with in the neck and axilla, the glands of which usually enlarge with great rapidity, and finally constitute bulky growths. The tumor itself is free from attachments, and the individual glands of which it is composed remain encapsulated and thoroughly independent of each other, ex-cept through their union by loose connective tissue, are generally kidney-shaped, or long-oval, and of a soft, semielastic consistence, movable under the skin, free from pain, or nearly so, and tolerant of rude manipulation. Their sectional surface is of a grayish, light-pink, or reddish-yellow color, sometimes mottled with minute points of extravasated blood, and yield on pressure a whitish, lactescent juice, not unlike that of encephaloid carcinoma.
The minute appearances are well exhibited in fig. 35, from O. Weber, representing a fine section of an enormous tumor of this description removed from the axilla of a boy. At c, the delicate meshes of the reticulated struma are seen, freed from the corpuscles by pencilling; while at a and b, the alveoli are crowded with lymph corpuscles, which at e and f are undergoing active proliferation by division and endogenous germination. In the soft form of lymphoma the lymph cells predominate, and the connective tissue of the

follicles exists as a very delicate reticulum, while in the firm variety the reticulated stroma is much increased in thickness and the cells are diminished in number.

These tumors are most common in adults between the ages of twenty and thirty-five, but they are sometimes observed in children. Their ordinary course may be thus described : Commencing on one side of the neck, for example, usually below the angle of the jaw, all the glands are successively invaded until the great anterior and posterior triangles and the supra-clavicular fossa are filled by the growth. After a period, which varies from four to eighteen months, the glands of the axilla and the opposite side of the neck become involved, followed by those of the mediastinum, bronchiae, and mesentery, as is indicated by chest troubles and impairment of the general nutrition. The patient is pale, weak, anemic, has a poor appetite, sleeps badly, becomes dropsical, and finally dies utterly exhausted.

The diagnosis of the disease in its earlier stages from simple inflammatory or scrofulous enlargement of the glands is impossible ; but its signs are so characteristic after it has made some progress that its nature is unmistakable. Its distinctive features are, its occurrence in young and vigorous subjects ; its limitation to one side of the body ; its progressive, rapid, and indolent growth, without any tendency to suppurate or extend beyond its capsule and to infiltrate the adjacent tissues ; the mobility of the glands under the skin ; the natural condition of the skin in regard to color and freedom from adhesions ; the successive involvement of the contiguous glands ; its elastic consistence and lobulated outline ; and, finally, the absence, in its early stage, of a cachectic state of the system. Lymphosarcoma, on the other hand, occurs later in life ; is painful ; usually commences in a single gland ; soon extends beyond the limits of its capsule to infiltrate the adjacent tissues, and convert them into a fixed, confused, and inseparable mass, and the overlying integument rapidly becomes adherent and discolored, and finally ulcerates.

Lymphomatous tumors, considered in the restricted sense in which they are here described, are of evil import. The firm form frequently recurs after extirpation, and progresses more tardily to a fatal termination than the soft variety. The latter, which is the more frequent, is excessively liable to occasion secondary deposits in the lungs, liver, spleen, kidneys, mediastinal, bronchial, mesenteric, and retroperitoneal glands, the intestinal tract, the osseous system, and the brain, and in point of malignity is not surpassed by carcinoma.

The most important remedies are chalybeate tonics, quinine, cod-liver oil, nutritious food and drinks, and a change of air. Mercury is generally hurtful, and friction with stimulating liniments and unguents should be avoided. From the arsenical treatment, so much lauded by some German surgeons, which consists in the exhibition of Fowler's solution in gradually increasing doses, and the injection of that remedy into the tumor, I have not met with decided results, nor have I been more successful from extirpation. The disease is very liable to go on from bad to worse despite all our attempts to arrest its progress, death finally taking place from sheer exhaustion.

SECT. IV.—NEOPLASMS WHICH REPRESENT EMBRYONIC, IMMATURE, OR UNRIPE CONNECTIVE TISSUE.

1. SARCOMATOUS TUMORS.

Sarcoma embraces an entirely distinct class of tumors, which hold an intermediate position between benign and malignant growths, inasmuch as they have a local, innocent period, during which they are amenable to the knife, while later they may assume a malignant form, as exhibited by their constant tendency to recurrence after removal, and the development of metastatic or secondary deposits in distant tissues and organs. It is by far the most interesting of the histoid neoplasms, presenting, as it does, in its clinical history, features similar to and yet dissimilar from those of carcinoma, and differing widely from the latter in its histological construction, the distinction between them being that carcinoma is characterized by a marked alveolar formation of its stroma, the loculi being crowded with cells of an epithelial type, while in sarcoma the cells are of the type of the developmental series of the connective tissues, and mingled with the intercellular substance. In its pure form, no tumor can be more simple in its character, as it consists of imperfectly elaborated elements, which have no similarity to any normal structure of adult life, and which never advance to higher development. A sarcoma may, therefore, be defined to be a tumor composed almost entirely of cells, which have their origin in those of the connective tissues, and persist as such, although greatly enlarged and increased in number. The structure of such a growth is, then, only distinguishable from that of the

connective-tissue series, by the excessive preponderance, development, and arrangement of its cellular elements, which constitute its peculiar features.

The connective tissues proper, whether subcutaneous, submucous, subserous, intermuscular, or fascial, are always the starting-points of sarcoma. It often, however, arises from other structures of this series, as, for example, the delicate, supporting, retiform tissues of the nervous centres and the lymphatic glands, the periosteum and osseous marrow, when the histological peculiarities of the matrix are usually propagated to it. Thus, sarcomas of the choroid and skin produce pigment cells; spindle cells predominate in those which originate in aponeuroses; while periosteal sarcomas evince a disposition to osseous formations, so that they are distinguished by the similarity of their structure to one or another of the group of connective tissues, as fibrous, mucous, glious, lymphoid, cartilaginous, osseous, or pigmented. They may, moreover, spring from the connective tissue of other neoplasms, as is frequently seen in carcinoma, some segments of which present sarcomatous characters, and they possess, in a remarkable degree, the power of combining among themselves, several different tissues existing in the same growth, thereby giving rise to mixed tumors.

The cell elements of sarcoma, like those of the tissues from which they are developed, are round, spindle-shaped, or stellate, existing either separately or in conjunction in the same tumor. In the latter event, the most common of all, one form always predominates, and it is in accordance with the preponderance of one or the other kind of cell that three principal forms of sarcoma are recognized, namely, round-celled, spindle-celled, and giant-celled. In all of these the cells, as a rule, are hypertrophied; the nuclei and nucleoli are especially enlarged and increased in number, the former often attaining the size of the largest normal cells. Round cells are found in all sarcomas, and are often very small, as is seen particularly in the glious variety. They are extremely friable, thereby producing the appearance of free nuclei in recent preparations, and, for the most part, resemble lymph corpuscles, colorless blood corpuscles, and granulation cells, from which they cannot be distinguished, unless it be by the relatively large dimensions of the nucleus, and, occasionally, of the cell itself. Spindle cells are very easily recognized. They consist of a dimly granular, pale, fusiform body, which terminates at each end in a long, delicate, perhaps subdivided, filamentary process. The nucleus, which contains one or more nucleoli, is usually single and well defined, and of an ovoid or elliptical form. Giant cells, which are commonly associated with the round and fusiform elements, are very characteristic, and are similar to the flat protoplasms that are found in the marrow of fœtal bones. They are the largest of human cells, and often attain extraordinary dimensions. Their substance is finely granular, and contains very numerous, not unfrequently even hundreds of oval, nucleolated nuclei. Their form, which is very variable, is generally irregularly ovoidal or polygonal; and rounded or filamentous processes not unfrequently shoot out from their bodies.

The form and number of the cells are so varied that they cannot alone be considered as decisive of the variety of the sarcoma, but it is their arrangement and development that are characteristic, as will be seen when the structure of the different tumors of this group is considered. They are placed side by side, either in contact with each other, or only separated by a minimum quantity of intercellular substance, the nature of which determines, in great measure, the subdivisions of sarcoma, but not of the sarcoma itself.

The matrix, or intercellular substance, is rarely collagenous or pure connective tissue capable of yielding gelatine on boiling, but generally of an albuminous, mucous, or glious nature. It is always present to a greater or less extent, and may be homogeneous, granular, or fibrillated. It occurs in small proportion in spindle-celled and giant-celled tumors, but is very abundant in the soft, rapidly-growing, small-celled sarcomas, imparting to them a sensation of fluctuation. In fibrous sarcomas it is distinctly fibrillated; in the lymphoid variety it forms a delicate network; in glious and some mucous sarcomas, it is usually amorphous and granular; while in some again of the latter it is frequently hyaline and homogeneous. Finally, one variety of cell may form the matrix of a tumor composed of an entirely different cell, and it is not at all uncommon for spindle cells to play this rôle in gaint-celled sarcomas of the bones.

Bloodvessels exist in great abundance in all sarcomas, pervading them in every direction, and forming more or less loose capillary networks, in the meshes of which the cells are contained. When the vessels are large, they are surrounded by a supporting connective tissue, which assists in giving a retiform appearance to some tumors, but when they are minute the cells, like those of granulation tissue, lie directly in contact with their walls, from which it is difficult to isolate them. In soft sarcomas, the capillaries are

rarely seen to consist of proper walls, but their lumen appears to be limited by round or spindle cells, and this disposition of their constituent elements, or vascularization of an almost purely cellular tissue, serves as a point of distinction between these and other neoplasms. In some cases the vessels are greatly enlarged, and are so numerous as to constitute telangiectatic or erectile sarcomas, which, from their great tendency to hemorrhage, represent one of the forms of fungus hematodes of former writers. In other cases they give rise to pulsating tumors, containing collections of blood, which include, in part, those formations known as aneurism of bone.

Of the causes of sarcoma little is known; for, although it sometimes shows itself soon after birth, it is doubtful whether it is ever of an hereditary character; it is often spontaneous in its origin, but is most frequently traceable to local irritation and external injury.

It appears in both sexes with about equal frequency, and, although it may occur at any period of life, is generally met with between the twentieth and the fortieth year, being rare before the second decade and uncommon after the latter period. The age of the patient, however, influences the liability of the affection in different organs. Thus, medullary sarcoma of the genital organs, particularly of the testicle, is more frequent about the age of puberty; retinal glious sarcoma is almost peculiar to infancy; osseous sarcoma is most common in young persons, while pigmented sarcoma usually occurs late in adult life. No reliable data exist as to the relative frequency of the seat of the disease. It is most common in the skin and subcutaneous and intermuscular connective tissues of the extremities. Periosteum and bone, particularly the epiphyses of the long bones and the maxillæ, are highly obnoxious to it. It is more rarely met with in the lymphatic glands and the secreting glandular organs; among the latter, the female breast and the testicle are its favorite seats. The eye is not unfrequently affected; while the serous and mucous membranes occasionally are its primary seats.

Sarcomas usually arise in the form of nodules, single or multiple; they may be firm or soft, and are distinguished from all other neoplasms by the rapidity of their growth, through which they often, in a short time, attain enormous dimensions, as is seen particularly in those connected with the periosteum and lymphatic glands. This increase in volume is, in part, central, through proliferation of preëxisting cell elements, and, in part, peripheral, by extension to the continuous tissues. If the former process predominate, the tumor is incapsulated, as is exemplified in fibrous sarcomas; whereas if the growth be due to extension by local infection, it is diffused, as is witnessed in soft, small-celled sarcomas. Their tendency is progressive. Although there may be a temporary arrest of development, extending even through a number of years, during which they are stationary, they usually, under the influence of some exciting agent, external or constitutional, awaken into activity and proceed regularly to their termination. Retrogression, through fatty metamorphosis of the cells, is almost constant in old, voluminous tumors, but it is rarely observed to affect the entire mass. The central part may recede, but, at the same time, the remainder increases more luxuriantly, and there is probably not a well-authenticated case on record of a spontaneous cure through absorption of the emulsified fatty detritus. Fatty degeneration occurs generally in those forms which are very soft, rich in cells, and increase rapidly, as the glious and mucous medullary sarcomas, converting them into a caseous material, resembling broken-down gummy substance. Through the same change, the harder, fibrous forms are converted into dense cicatricial tissue, poor in cells, not unlike that of atrophic scirrhus; but cicatricial shrinkage is uncommon. Calcareous and osseous transformations take place in portions of those tumors which are connected with bone, as is evinced by the production of irregular, radiating, delicate spicules or plates. At other times, and especially in large, medullary growths, softening ensues, which may end in ulceration; or the detritus may be absorbed, leaving cavities, which become filled with a serous fluid, thereby forming species of cysts. In some cases, during the process of softening, the bloodvessels are eroded, causing extensive parenchymatous hemorrhage, in which event the sarcoma, now and then, is converted into a species of blood cyst, obscuring the original characteristic elements, which can then be discovered with difficulty, and only at the periphery. Sarcomas of the skin ulcerate early, but the destruction is not great. In general, these tumors exhibit little tendency to ulcerate, particularly the firmer forms, for which reason the fibrous sarcomas may attain an enormous size. The soft, rich-celled sarcomas are more disposed to this change, but it appears later than in carcinoma. When it has once occurred, the ulcer rapidly increases, has a foul, fungous appearance, and the accompanying discharge, often bloody, sometimes putrid, is very abundant. If the hemorrhage and suppuration are profuse, symptoms of anemia rapidly supervene. Coincidently

with, but seldom before, the ulceration, pain sets in, the general strength fails, the internal organs become affected with secondary deposits, and the patient finally succumbs either from complications or accidents due to metastatic infection, septicemia, or exhaustion, induced by the combined effects of anemia, prolonged suffering, and profuse discharges of blood and pus.

Malignity is a very decided attribute of sarcomas, exhibiting itself not only in a constant tendency to local recurrence, after extirpation, but also in its power of metastatic diffusion. Locally, the infection extends, first, to the neighboring homologous tissues, often far beyond the apparent limits of the tumor, a circumstance which explains its disposition to repullulation; and, subsequently, it advances, by continuity, to the heterologous tissues. Secondary nodules, often in enormous numbers, and almost invariably presenting the same type as that of the original affection, also develop in distant organs, as the lungs, liver, kidneys, brain, bones, pleura, and peritoneum. This dissemination of sarcoma takes place, as a rule, through the blood, either by the passage of infecting juices, germs, or cells into the vessels, or by embolism, and very rarely by the lymphatics. The lymphatic glands are either not affected at all, or they become involved very late in the disease; and the lymphatic vessels themselves are seldom occupied by sarcomatous cells. This immunity of the lymphatic system is peculiar, and serves to distinguish this class of tumors from carcinoma. The most distant organs, as, for example, the lungs, in osseous sarcoma of the extremities, are frequently involved, without the intervening lymphatic glands being at all affected.

From the preceding general description of the clinical progress of sarcomas it is evident that they bear a certain resemblance to carcinomas, but differ from them in the following particulars. After extirpation, they almost certainly return, representing the peculiarities of the original tumor, in or near the cicatrice, and this local recurrence is constantly repeated. In carcinomas, on the other hand, continuous recurrence usually is the rule. Sarcomas evince little disposition to open; they rarely give rise to a true cachexia; are almost painless before ulceration sets in; and the neighboring lymphatic glands are singularly free from implication. These distinctive features are reversed in carcinoma. To the naked eye, the only differential characteristics, so far as we are aware, are that the former are frequently incapsuled, fat is never seen in their interior, and they do not contain a juice like that of carcinoma, which can be expressed from an alveolar structure. The anatomical distinctions are not less marked, the relation borne by the cell to the intercellular substance being decisive of the nature of the mass. In carcinoma, alveoli are formed between the trabeculæ of the fibrous stroma, which are crowded by cells of an epithelial type. In sarcoma, on the other hand, the cells are arranged as parenchymatous cells, forming component parts of a continuous tissue; and the structure is never, in the true sense of the term, alveolar, in such a way that the cell elements, which always preserve the type of connective-tissue cells, are loosely grouped in the particular meshes of a stroma.

The tendency exhibited by sarcomas to local recurrence and general diffusion warrants the surgeon in regarding them as malignant formations, thereby rendering the prognosis in the highest degree unfavorable. This is particularly true of the soft varieties which are rich in small cells, whether round, fusiform, or stellate, with an abundant intercellular substance, and they include the greater number of those tumors known as medullary and hematoid fungus. They soften, and ulcerate early, bleed easily, and rapidly disseminate themselves throughout the organism. As a rule, local and general infection commence soon, and exist, although inappreciable to the eye and touch, at the time of operative interference, on which account rapid repullulation is witnessed. In these cases the prognosis, before operation, must, of necessity, be guarded, inasmuch as an important element, which guides the surgeon in carcinoma, namely, involvement of the lymphatic glands, is generally absent. The diffused forms are more infectious than those which are isolated or incapsulated, and the firm sarcomas are more benign and pursue a less rapid course than the soft. It is, moreover, important to remember that, at an early period of their development, particularly if their growth has been tardy, they are local, relatively benign affections, attended neither with pain, inconvenience, nor detriment to the general health, and amenable to operation, good results being occasionally obtained after amputation even in large osseous sarcomas of the extremities.

The degree of malignity of sarcomas differs, although it is not easy to establish the gradation. In general, however, it may be stated that soft tumors which are rich in small cells are more destructive to the part, as well as to life, than those with large cells, medullary giant-celled and colossal spindle-celled sarcomas even affording a comparatively favorable prognosis. Fibrous sarcomas are usually solitary, and, hence, are more benign

than the former. Glious, myxomatous, and pigmented tumors, with small cells, on the other hand, do not yield to carcinoma in respect to malignity. In other words, the greater the tendency to the production of more highly developed structures, as connective tissue and bone, as seen in the spindle and giant-celled sarcomas, the less grave is the prognosis; while it becomes more serious the more the tumor is formed entirely, or nearly so, of rudimental or persistent developmental tissue. In the order of malignity, the sarcomas may, therefore, be classed as follows—medullary round-celled, pigmented, alveolar, osteoid, myxomatous, lipomatous, spindle-celled, fibrous, and giant-celled. It may, however, be remarked that the prognosis is influenced by the organ or tissue affected, as well as by the structure of the tumor itself. Thus a sarcoma of the testicle is more malignant than the same variety affecting the ovary. Sarcoma of the aponeuroses gives a favorable prognosis, while in some of the mucous membranes local and distant infection rapidly supervenes.

DIFFERENT FORMS OF SARCOMA.

1. *Round-celled Sarcoma.*—Round-celled sarcoma, known also as the embryoplastic tumor, or soft, medullary, granulation, glious, lymphadenoid, or encephaloid sarcoma, is most frequently met with in young persons, and during infancy, in connection with the periosteum and the neuroglia, or delicate supporting reticulum of the retina and nervous centres. It is, however, not uncommonly observed in the skin, subcutaneous and deep connective tissues, bones, muscles, testicles, and glands, especially the lymphatic and mammary, and must be regarded as the most malignant of all growths, not carcinomatous, as it runs a very rapid course, attains huge proportions, soon ulcerates, bleeds easily, almost always, if not invariably, returns after extirpation, and possesses great powers of general dissemination, the lungs being then, apparently, its favorite seat.

On section, the cut surfaces are occasionally so soft and white as to resemble brain matter; but they usually have a translucent, light-grayish appearance, which may be tinted of a pinkish or yellowish hue, or be variously mottled by extravasated blood and injected vessels, which are very numerous and of a large size. They also furnish, on pressure or scraping, a transparent fluid, altogether different from the so-called cancer-juice. This is a peculiarity not met with in the other varieties of sarcoma, excepting the soft spindle-celled. From their naked-eye appearances, as well as from their clinical history, these growths are constantly mistaken for

Fig. 36.

Minute Structure of Lymphadenoid Sarcoma.

encephaloid carcinoma, and the difficulty of distinction between them is sometimes very great, if not insurmountable, without the aid of the microscope. In its minute structure, round-celled sarcoma is composed essentially of delicate bloodvessels and spherical, fragile cells, provided with a round or oval nucleus, and of the dimensions of lymph corpuscles, and contained in a homogeneous, dimly granular, or amorphous matrix, thereby bearing a great resemblance to granulation tissue. There are several varieties of round-celled sarcoma, which are based upon the nature of the intercellular substance, and upon certain degenerations.

a. Lymphadenoid sarcoma.—The lymphatic gland-like round-celled sarcoma is distinguished by a delicate reticulum similar to that of adenoid tissue, pervaded by large, thin-walled capillaries, which are formed of only one cell layer, as is shown at *a*, fig. 36, from Rindfleisch. The spaces between the vessels are occupied by the reticulum, the meshes of which contain lymphoid cells, with relatively large nuclei, each of which includes from one to three nucleoli, as shown at *b*. This variety of tumor is very soft, and is found more particularly in the superficial and deep-seated connective tissue of the thigh, and the periosteum and medulla of bones.

β. Glioma.—Glious sarcoma proceeds from the neuroglia, or cementing substance of the central nervous system, and is essentially composed of small round cells imbedded in a granular matrix. It differs from all other tumors of this class in being seated only in the brain, spinal cord, and the soft nerves which proceed from the brain, as the optic and its

retinal expansion, the trigeminal, and the auditory. Virchow teaches that the nervous elements which normally exist in the neuroglia, disappear in these growths, but Klebs has conclusively shown that in their earlier stages they contain ganglion cells and medullated nerve fibres, on which account he terms them neurogliomas. However this may be, glioma frequently has a soft cerebriform section, infiltrates the adjacent tissues, and occasionally reproduces itself in the internal organs. It is most frequent in infancy and early childhood in the retina.

γ. Alveolar sarcoma.—A still wider departure from the ordinary type is observed in the tumors originally described by Billroth as alveolar sarcoma, an illustration of the minute appearances of which is afforded by fig. 37, copied from that author. Roundish heaps of comparatively large cells, which look not unlike giant cells, are contained in the spaces of a connective-tissue meshwork, the coarser trabeculæ of which give off delicate bands that intersect the masses of cells and divide the larger clusters into smaller ones. It is this peculiar arrangement of the intercellular substance, along with the lymphoid character of the cells,

Fig. 37.

Minute Structure of Alveolar Sarcoma.

which serves to distinguish this neoplasm from carcinoma, as well as to exclude the term sarcomatous carcinoma, which Rindfleisch has applied to it.

Alveolar sarcoma is an uncommon, but a highly vascular growth, and constitutes a certain proportion of the so-called aneurisms of bone. It is met with in the bones, muscles, and skin; and it is as malignant as carcinoma.

δ. Lipomatous sarcoma.—The lipomatous sarcoma is not a rare form of the medullary round-celled sarcoma, in which a limited number of the cells are distended with drops of oil without being destroyed, thereby giving rise to an irregular infiltration of the mass. Its favorite seat is the subcutaneous connective tissue of the extremities, where it forms large tumors, which may be confounded with encephaloid carcinoma, but from which they may be easily distinguished with the aid of the microscope. Lipomatous sarcoma returns, as such, after extirpation, rapidly infects the neighboring lymphatic glands, and disseminates itself throughout the organism; the secondary deposits, however, retaining the type of the medullary round-celled sarcoma.

ε. Myxomatous sarcoma.—The myxomatous sarcoma is an outgrowth of early and extensive mucous transformation of the round-celled sarcoma, and derives its name from the peculiar tremulous, gelatinous appearance presented on section. It is very decidedly malignant, grows rapidly, and acquires a large volume, particularly when fatty infiltration is combined with the mucous change. These characters, when considered in connection with its infecting powers and its minute structure, serve to distinguish it from the ordinary myxomatous tumor. It has been observed in the omentum, the back, the skin, and the connective tissue of the extremities.

2. *Spindle-celled Sarcoma.*—Spindle-celled sarcoma has various synonymes, of which the most common are fibroplastic tumor and recurring fibroid, although it is also designated as fasciculated sarcoma, albuminoid sarcoma, and plasmoma. It is met with chiefly in certain growths of cicatrices and of the skin, known as keloid, and seems to have a predilection for aponeuroses, the sheaths of bloodvessels and nerves, and the subcutaneous and intermuscular connective tissues of the extremities and the neck. It is also found in periosteum, bone, the testicle, female breast, and uterus, and differs from the preceding variety in exhibiting rather a proneness to local recurrence than to general infection. In one of my cases, the growth was removed four times in ten years, and instances are on record, in which the disease, appearing primarily in young adults, has returned and been extirpated, at or near the site of the first operation, as often as five or six times, at considerable intervals, and yet the patient attained a good old age.

The most interesting and extraordinary example of recurrence, probably, ever recorded,

is one which has been for upwards of ten years under my personal observation, and which was described in former editions as encephaloid carcinoma. Reëxamination, however, proved it to be composed of sarcomatous cells, in which the small spindle forms preponderated. The patient, an unmarried woman, aged forty-four, in March, 1857, perceived in the left breast a small tumor, which was excised the following October. During the next sixteen months two more operations were performed, but as the mammary gland had only been partially removed, I extirpated the whole of it, along with a fourth tumor, in May, 1859, when the case was placed under my charge by Dr. Russell, of this city. The disease soon reappeared in the cicatrice, and in three months and a half again required the use of the knife. After four operations by myself, the case fell into the hands of one of my former clinical assistants, Dr. Asch, who attended her until May, 1861, when she was again put under my care. In September of that year, I performed the twenty-third and last operation. The number of tumors removed, from first to last, was fifty-two, varying in size from a small almond to a pullet's egg. They generally recurred at or near the cicatrice within a few weeks after extirpation, and speedily assumed a fungating appearance. They were of a soft, vascular, brain-like structure, and the seat of a thin, fetid discharge, with little or no disposition to bleed. Occasionally the woman complained of sharp, shooting pains in the tumors, extending to the shoulder, but the local suffering was commonly very slight. Her general health was all along excellent; there was no lymphatic involvement in the axilla or elsewhere; menstruation was going on well; and she always rapidly recovered from the effects of the use of the knife.

Ten years have now elapsed since the last operation. The cicatrices are all in a sound condition, very soft, and of a whitish aspect. Large portions of the pectoral and also of the external and internal intercostal muscles, were cut away, so that during a deep inspiration there is a slight protrusion of the pleura. The apex of the heart is likewise partially uncovered. It is proper to add that eleven of the operations were performed in 1860, and six in 1861.

In its earlier stages, when cut, the spindle-celled sarcoma grates under the knife, and the surface exhibts a firm, tough, grayish, or pale yellowish appearance, similar to that of an ordinary fibrous growth. After repeated repullulation and removal, however, it becomes softer, more succulent and brain-like, and it may be accepted as a rule that entirely medullary, glistening-white tumors are composed of spindle-cells, which, however, rarely attain great size. Its texture is sometimes remarkably brittle, the slightest trac-

Fig. 39.

Fig. 38.

Minute Structure of Small Spindle-celled Sarcoma.

Minute Structure of Large Spindle-celled Sarcoma

tion separating it into numerous fragments, some of which are apt to be left behind during extirpation, unless great care is used in tracing them out.

Spindle-celled sarcoma, as seen in fig. 38, from Green, and in fig. 39, from Virchow, consists essentially of fusiform cells, with well-marked nuclei, and thin processes, sometimes split at the end, and often many times the length of the body of the cell. They may be closely aggregated, forming long bands, which give a trabeculated appearance to certain portions of the growth, or they may be arranged loosely in a radiating manner. The cells are imbedded in a granular, hyaline, or fibrillated intercellular material, which usually exists in small quantity.

The varieties of spindle-celled sarcoma are the fibrous and melanotic or pigmented.

a. Fibrous sarcoma.—The fibrous sarcoma is a variety of the fibrous tumor, from which, however, it differs in the relatively greater richness and development of its cell elements, and it includes those cases of so-called fibroma, which manifest a peculiar tendency to local return, and are occasionally followed by secondary deposits, particularly in the lungs and pleura. Tumors which possess these clinical features, and show, on minute examination, segments of pure sarcomatous cells, and segments of pure fibrous tissue, should be classed under this head. In such cases, either an old fibrous tumor takes on active growth through increase of its cell elements, or a fibroma with relatively less cell development recedes and approaches more and more the type of pure sarcoma. These growths arise chiefly from the fasciæ and periosteum, and are most frequently observed in connection with the nares and base of the skull and the superior maxillary sinus.

β. Pigmented sarcoma.—Pigmented or melanotic sarcoma, although pigmentation of the cells may be met with in any of the forms of sarcoma, is usually a variety of the spindle-celled tumor, in which the cells are more or less highly impregnated with melanin,

Fig. 40.

Minute Structure of Pig-
mented Sarcoma.

as in fig. 40, from Green. To the naked eye, it has either a uniformly dark-brown or black appearance, or it may be mottled, or present limited zones of pigmentation, the intermediate portions being white, gray, or translucent. From the cut surfaces a dark, creamy juice can be scraped, which, under the microscope, exhibits round and fusiform cells in different stages of infiltration, the structure of the tumor itself being composed generally of round cells lying in the interstices of a spindle-celled network, although a pure round-celled, or a pure spindle-celled, growth is occasionally met with. The most frequent seats of pigmented

sarcoma are the skin and choroid coat of the eye, but it sometimes arises primarily in the lymphatic glands. Its great malignity is shown by its tendency to rapid and almost universal dissemination, every organ and tissue being liable to be invaded by it. In this respect, it bears a striking similarity to melanotic carcinoma, from which, indeed, it is almost impossible to distinguish it. Both are of a medullary nature ; the latter contains, as a rule, few large cells of an epithelial type, and its alveolar structure disappears very early, the cell development soon predominating over the formation of a fibrous stroma. When the structure is spindle-celled, the distinction is readily made ; but when the tumor is round-celled, it is extremely difficult to discriminate between them. The occurrence of lymphatic involvement, however, may be of some value in forming a differential diagnosis. This, as has already been pointed out, is comparatively rare in sarcoma, and very common in carcinoma. Of 83 cases of melanosis, collected by Eiselt and Pemberton, in only 33 was there contamination of the lymphatic system, a circumstance rather in favor of the majority not being carcinomatous. These facts, however, show that pigmented sarcoma is probably of more frequent occurrence than has generally been supposed, and they entitle it to a place in the varieties of sarcoma.

3. *Giant-celled Sarcoma.*—This term is applied by Virchow to that variety of sarcoma in which giant or multinucleated cells form a regular and constant element, although it had previously been described by Lebert and Nélaton as the myeloplaxic tumor, and by Paget as the myeloid or marrow-like tumor. It has been noticed in the different parts of the body, but in particular in or upon bones, the jaw-bones and the epiphyses of the long bones being its favorite seats. It has also been observed in the mammary gland, uterus, cerebral membranes, the subcutaneous connective tissue, in the muscles, and in the eyelids and conjunctiva, occurring in various sized masses, generally of a rounded or ovoidal shape, and of a consistence varying from that of tallow or suet to that of fibrous tissue. The cut surface has a smooth, compact, shining, grayish-white or greenish appearance, with blotches of a dark crimson, brownish, pink, or modena hue, either uniformly, or in various degrees of combination, all these tints being sometimes commingled. Much stress is laid upon these colors by pathologists as diagnostic characters of giant-celled sarcomas, affording, as they do, the most ready external means of discrimination between them and analogous growths. When the disease is developed in the cancellous tissue of the bones, in which its occurrence is more frequent than anywhere else, the tumor disparts the compact layers, forming a kind of cyst-like expansion, in which the new matter is lodged, and which, under such circumstances, often contains a large amount of osseous substance, soft, cellulated, of a reddish or pale yellowish tint, and easily recognized by sight and touch.

The giant-celled sarcoma is generally rapid in its growth, and is not always a benign affection. It destroys effectually the structures in which it is developed, recurs locally after extirpation, and sometimes gives rise to metastatic nodules in the internal organs. It is, however, the least malignant of the sarcomas, and the prognosis is, as a rule, favorable.

The most characteristic minute feature of this tumor, as seen in fig. 41, from Lücke, is the preponderance of multinucleated, myeloplaxic, or giant cells, which never, however, exist alone, but

Fig. 41.

Minute Structure of Giant-celled Sarcoma.

are variously intermingled with round or spindle forms, and contained in a sparse, generally amorphous, sometimes fibrillated, intercellular substance.

In addition to the foregoing three principal forms of sarcoma and its varieties, there are certain other varieties, which will be described in their appropriate places under the heads of lymphatic, cartilaginous, and osseous tumors.

The diagnosis of sarcomas during life is by no means always easy. Their form is usually well defined, round, oval, or spherical, and their surface is more or less lobulated. Periosteal tumors of this description, however, may be distinguished by their smooth surface and fusiform outline. In consistence, they may be firm, tense, and elastic, but are generally soft and apparently fluctuating, so much so, indeed, that they may be mistaken for abscesses and the softer varieties of fatty and mucous tumors. The overlying integument may be unchanged, or it may be tense, florid, or livid, and, in some parts, ulcerated, the sore, in the latter event, being usually superficial and covered with healthy-looking granulations. The subcutaneous veins rarely attain any considerable volume. Their origin is commonly traceable to external injury. They sometimes grow slowly, at other times rapidly. In the case of a lady, thirty-five years of age, whom I saw with Dr. Addinell Hewson, a small, round-celled tumor of this kind in the mammary gland attained, in the course of four months from the time of its first appearance, a weight of nearly six pounds and a volume equal to an ordinary adult head. No pain attends these neoplasms until ulceration sets in, and even then it is often very insignificant. They are most frequent between the twentieth and fortieth years, rare before and after these periods, and very uncommon in young children. In a word, a very rapidly growing, large, painless, apparently fluctuating tumor, occurring before the fortieth year, not marked by lymphatic involvement, disposition to ulcerate, or impairment of the general health, may be pronounced to be sarcomatous.

In the treatment of these tumors nothing need to be expected from general measures, the only remedy that holds out the slightest prospect for a cure being early and complete excision, with, perhaps, destructive cauterization of the surrounding parts. For the very large, soft sarcomas which originate deep in the extremities, whether from the interstitial muscular tissue, lymphatic glands, aponeuroses, sheaths of vessels and nerves, periosteum, or bone, amputation, if possible, in the contiguity of the limb, is the proper resource, while resection may be practised when the shorter bones, such as the phalanges of the fingers, clavicle, radius, and ulna, are affected. When the jaws are the seat of the disease, total extirpation is preferable to partial excision.

2. MYXOMATOUS TUMORS.

The morbid product, originally described by J. Müller under the name of collonema, is now generally known as the mucous tumor, or myxoma, from the fact that it is essentially composed of mucous material, which thus imparts to it its distinctive features. In some pathological treatises it figures as a variety of sarcoma with the prefix "gelatinous" or "net-celled." Its characteristic mucous constituent is represented in the normal state by the jelly-like matter of the umbilical cord, by the subcutaneous connective tissue of the fœtus, and to a slight extent by the vitreous humor of the adult eye. A young myxoma
closely resembles, in its physical properties, a mass of fat; and cases are met with in which the one is directly convertible into the other by an increase or decrease of the respective constituent elements.

The characteristic features of the myxoma are elasticity and softness. Its consistence, however, is by means uniform. Occasionally the whole mass has a tremulous, jelly-like look and feel; sometimes it has an infiltrated, œdematous appearance, and readily pits on pressure; and now and then it fluctuates like a cyst. In rare cases these various properties are associated in the same specimen. The older growths are always harder than the recent, the former generally containing more solid matter and the latter more mucous.

Two essential elements enter into the composition of a myxoma, a fibrous basement structure and an intercellular substance, pervaded by bloodvessels, generally so distinct as to be easily recognized by the naked eye. The basement structure, the proper stroma of the tumor, belongs essentially to the developmental series of connective tissues, and yields on pressure, when cut, an intercellular substance of a glutinous, tenacious consistence, like the white of an egg, or a solution of gum arabic, perfectly free from milky juice. The fluid thus obtained exhibits under the microscope numerous cells, of varying forms and sizes, for the most part round, angular, stellate, spindle-shaped, or net-like. Many of the cells are of great length, as if they were beaten out, with very thin, tapering extremities. Some of the cells have several nuclei, others only one, and many of them are connected in such a manner as to present an appearance as if they were fused together.

Fig. 42.
Minute Structure of a Myxomatous Tumor.

In the young myxomatous growths, abounding in mucous material, the round and angular cells are most conspicuous, whereas in the old there is a preponderance of the stellate and spindle-shaped, which not unfrequently exhibit an anastomotic and areolar arrangement, rendered very distinct on the addition of a solution of iodine or carmine, as in fig. 42, from Lücke. Besides these elements, the morbid mass often contains fat cells, fibrous tissue, both white and elastic, cartilage and bloodvessels in varying proportions, thus giving rise to certain subdivisions, as the lipomatous, fibrous, cartilaginous, and telangicetatic.

Among the more perfect types of the mucous growths are the gelatinoid polyps of the nose, ear, and uterus, and the non-malignant colloid tumors, especially those developed in the parotid region, in the nerves, and in the mammary gland. They occur chiefly in young subjects, in the subcutaneous and intermuscular connective tissues, particularly upon the thigh, back, shoulder, neck, labia, and trunk, in the mucous cavities, in the hilus of the kidney, and in the nerves and bones, in the latter of which they usually take their starting-point in the medulla. More or less mucous matter, such as distinguishes the myxoma, is often found in goitrous and other cysts, serving to impart a mixed character to the morbid growth.

The myxoma has only a very feeble circulation, and is, therefore, usually of slow growth and of small size, although occasionally the tumor advances very rapidly, and acquires a large bulk. Such an occurrence will be most likely to happen when the morbid mass abounds in embryonic material and in round cells with several nuclei. Although generally essentially benign, mucous tumors may, by their active proliferation, and their remarkable power of combining with other tumors, occasionally assume a decidedly malignant character, as evidenced by their frequent recurrence, and the formation of secondary deposits in the viscera. The latter occurrence is most frequently witnessed in the lipomatous variety, since of seven cases of which I am cognizant in only two was the tumor of a hyaline nature, while it was lipomatous in the remainder.

The myxoma is liable to hemorrhage from the accidental rupture of its vessels, but it rarely, if ever, ulcerates or mortifies. The older portions often undergo the fatty degeneration, and such portions are occasionally occupied by cartilaginous, or osseous matter, as the result of a retrogressive movement.

The diagnosis of such a growth cannot be easily solved before extirpation, except when

it occupies a mucous canal. When situated under the skin or among the muscles, its slow development, its soft, elastic consistence, its mobility, the integrity of the general health, and the absence of pain, discoloration of the skin, and involvement of the neighboring lymphatic glands may assist, but cannot positively determine, the diagnosis.

No remedies, local or general, exert any control over this variety of morbid growth. Removal is effected, according to the situation and volume of the mass, with the forceps, ligature, écraseur, or knife. Recurrence will not be likely to happen if the operation be well performed.

SECT. V.—NEOPLASMS DERIVED FROM AND COMPOSED OF HIGHER TISSUES.

1. MYOMATOUS TUMORS.

Under the term myoma may be described a tumor which is composed of muscular tissue. It embraces two varieties of growths, namely, a neoplasm containing striated muscular fibres, and a neoplasm containing smooth muscular fibres.

Fig. 43.

Minute Structure of Rhabdomyoma.

1. Myoma composed of striated or voluntary muscular fibres, or the rhabdomyoma of Zenker, is very rare, but it has been observed in the kidney, heart, uterus, testicle, in the muscles of the arm and chest, the vagina, and at the root of the nose. It consists, as is seen in fig. 43, from Rudnewa, of striated fusiform cells, with a varying amount of connective tissue. It is frequently congenital; may attain the volume of an adult head; is now and then combined with sarcoma or myxoma; and is liable to recur after extirpation.

2. Myoma composed of smooth muscular fibres, or the leiomyoma of Zenker, finds its characteristic type in the uterus. In structure, as seen in the adjoining sketch, fig. 44, from Arnott, it is made up of parallel or interlacing bundles of unstriped muscular fibres, or of elongated spindle cells with rod-shaped nuclei united by connective tissue. A few fat cells are shown in the illustration.

Leiomyoma occurs almost exclusively in the involuntary muscles, those of animal life being in great degree exempt from it. Although it is occasionally met with in the œsophagus, prostate, vagina, bladder, testicle, stomach, intestine, skin of the scrotum and mammary region,

Fig. 44.

Minute Structure of Leiomyoma.

its favorite seat is the uterus, especially the body of that organ, for the reason, apparently, that this part is much more abundantly supplied with muscular fibres than the cervix. In the organ in question it occurs in three distinct situations, as an intramural, intraparietal,

or extramural growth, capable in all of attaining an enormous bulk, cases having been observed in which the weight nearly equalled that of the body of the patient. When such a growth is developed in the cavity of the uterus, it is generally described as a polyp, although its structure does not differ from that of a myoma in the other situations referred to. In shape the tumor is, for the most part, globular, conical, or pyriform, its attachment being either by a broad base, or, as is most commonly the case, by a comparatively narrow pedicle, especially when the growth is of the polypoid variety.

The number of muscular tumors is variable. In the uterus it is often considerable, especially in the extramural variety, in which there are occasionally as many as half a dozen, or even more. In their color they are light-grayish, pale-reddish, or almost white. Their consistence varies with their age and other circumstances. Young growths of this kind are often quite soft, succulent, and even slightly elastic, whereas the older ones are very firm and dense, creaking under the knife, and tearing with great difficulty. Many, especially the older ones, contain a large proportion of fibrous matter, and, hence, such growths are usually called fibro-myomas, or fibro-muscular tumors. Calcareous matter and cysts, filled with different kinds of fluids, are also occasionally found in them; and many, as they advance in age, undergo the fatty degeneration.

A myoma is occasionally met with in the prostate gland, chiefly of elderly subjects, as an outgrowth of the normal muscular fibres, which are prolonged upon the organ from the muscular coat of the bladder. A very large proportion of the structure of this gland is, as is well known, made up of these prolongations, interspersed with the peculiar glandular substance from which the organ derives its distinctive features. The part of the gland most liable to this growth is the posterior and middle, where it occurs in various forms and degrees, constituting what is called the middle lobe, a structure which has no existence in the normal state. Small nodules of this kind are occasionally imbedded in the main body of the gland, inclosed in a distinct capsule, and easily enucleated.

The myomatous tumor is most common in advanced age. In the uterus it seldom appears before middle life, and is most frequent in elderly subjects. It is never congenital. It is generally tardy in its development, has a very scanty supply of bloodvessels, and incommodes chiefly by its weight and bulk, and by its encroachment upon the surrounding parts. In the cavity of the uterus it usually gives rise to hemorrhage, and in the prostate gland to serious obstacle to the passage of the urine.

Of the causes of these formations nothing whatever is known. Inflammatory irritation may possibly have some agency in their production, but in what manner or degree, is wholly conjectural. That they are merely so many benign outgrowths or hyperplasias of the normal tissues of the organs in which they are developed, is sufficiently evident.

Medication exerts no influence upon the progress and ultimate fate of this morbid growth. When seated in the cavity of the uterus, it is often susceptible of removal, particularly when it has a narrow pedicle, with the forceps, ligature, or écraseur. Occasionally a tumor of this kind may be enucleated; and now and then a case occurs of spontaneous expulsion, especially when the growth has undergone calcification, or when it has been partially devitalized by incisions and the injection of irritating fluids. Myomas of the prostate are irremediable.

2. VASCULAR TUMORS.

The vascular tumor, angioma, or erectile tumor, essentially consists, as the name implies, of a network of small vessels, mostly of new formation, and held together by a minute quantity of connective tissue. Its characteristic type is found in what is called a mother's mark, nævus maternus, capillary angioma, or telangiectasis, a term much employed by German pathologists, and literally signifying a dilatation of the capillary vessels. Aneurism by anastomosis, so graphically described by John Bell, early in the present century, is a not uncommon form of vascular tumor. The term erectile, as applied to these morbid growths, is, in the main, well chosen, as their structure bears, in many instances, if not generally, a very close resemblance to the cavernous body of the penis and similar erectile textures, expanding under mental emotion and whatever has a tendency to cause a temporary influx of blood.

The vascular tumor is generally met with as a congenital affection, its foundation being laid during fœtal life, and it is not uncommon for it to acquire a considerable bulk before birth. Most generally, however, it is very diminutive when first noticed, not exceeding, it may be, the volume of a pin's head, a millet seed, or a currant, and it often continues so until some time after, when, perhaps suddenly, and without any assignable cause, it

takes a new start, growing with remarkable rapidity, and encroaching more or less seriously upon the surrounding structures. The ordinary sites of angioma are the skin and mucous membranes, especially about the head, face, eyelids, lips, cheeks, and tongue. An internal hemorrhoidal tumor is essentially an erectile angioma.

Vascular tumors vary much in their color, the chief influencing causes being their structure and situation. The venous are usually of a bluish, deep lilac, claret, or purple hue, whereas the arterial are generally of a bright rose or scarlet color, in consonance with the nature of their contents. The color, however, is not always uniform, but often varies in different portions of the same growth. In their consistence they are soft and spongy, easily compressed, and often notably elastic, especially when of large bulk, of long standing, or deeply seated. An arterial angioma—the true anastomotic aneurism—always pulsates synchronously with the heart, and, as already stated, greatly augments in bulk under mental excitement; but it rarely has any of the sounds so characteristic of a common aneurism.

Fig. 45.

Vascular Tumor of the Scalp.

There is generally only one such tumor; but we often meet with several in the same patient, and in some of my cases the number was so great as to lead to a belief in the existence of a kind of angeiomatous diathesis.

Although most vascular tumors are congenital, they occasionally do not make their appearance until a long time after birth. How far external injury, as a blow or bruise, may be instrumental in giving rise to such formations is undetermined. There are, however, numerous instances upon record which go to show that it may act as an exciting cause. In a case related by the late Dr. J. Mason Warren, a man, thirty-six years old, had a large aneurism by anastomosis on the lobe of one of his ears, consequent, apparently, upon a severe frost-bite, received at the age of sixteen.

Fig. 46.

Minute Structure of Simple Angioma.

Fig. 47.
Minute Structure of Cavernous Angioma.

The vascular tumor exhibits considerable variety of structure, being at one time essentially composed of veins, at another of arteries, and occasionally, again, of both arte-

ries and veins, so equally balanced, in number and calibre, as to render it difficult, if not impossible, to determine which predominate. In the simple angioma, which embraces the various forms of telangiectasis and nævi, the vessels, arterial, venous, or capillary, are greatly enlarged, tortuous, and anastomose, as in fig. 46, from Billroth. In the cavernous angioma, or cavernous venous tumor, which comprises erectile tumors and aneurism by anastomosis, the structure, as displayed in fig. 47, from Rindfleisch, is very similar to the cavernous body of the penis, being composed of a reticulated meshwork of dense and elastic connective tissue, lined by endothelium, and distended with blood. The meshes or alveoli freely intercommunicate, and constitute a system of cavities in which the blood carried to them by numerous vessels circulates. Old angiomas sometimes contain phlebolites and organized clots. Numerous instances are recorded in which the patient bled to death in attempts to extirpate such tumors.

The diagnosis of angiomas is deduced from their situation, color, and consistence, and from a careful consideration of the history of the case. The prognosis varies. The venous tumor is always less dangerous than the arterial, which, as it enlarges, is liable, especially under the influence of injury, ill-health, or exhausting disease, to ulcerate, to bleed, and to cause absorption of the surrounding structures, the osseous and cartilaginous not excepted. Some growths of this kind, arterial as well as venous, occasionally enjoy a period of repose, apparently neither advancing nor receding; generally, however, the reverse is the case, there being a disposition to rapid development, the more especially when there is a marked predominance of the arterial element, or when the tumor is almost exclusively composed of this structure. A spontaneous cure occasionally occurs, the vessels becoming obliterated, probably as an effect of inflammation leading to the coagulation of their contents and the gradual closure of their calibre. Recurrence has been witnessed after excision, probably due to the imperfect use of the knife rather than to any inherent tendency to repullulation. Carcinomatous or sarcomatous degeneration is possible, but very uncommon. The treatment of angiomas will be fully discussed in the chapter on the affections of the capillary vessels.

3. LYMPHANGIOMATOUS TUMORS.

Tumors composed of newly-formed and of dilated preëxisting lymph vessels are uncommon, but their existence is confirmed by a number of examples which have been recorded during the past fifteen years, and which have been carefully studied by Wegner in an elaborate paper published in the Archiv für Klinische Chirurgie for 1877.

Lymphangioma may be simple, cavernous, or cystoid. The simple variety consists of an anastomosing network of lymphatics supported by a slight quantity of connective tissue, so that it resembles simple or plexiform angioma. Cavernous lymphangioma is composed of a trabecular cavernous tissue, the meshes of which are filled with fluid or thrombosed lymph. Hence it has the same anatomical construction as cavernous angioma or venous tumor, the only difference being that its meshes contain lymph instead of blood. The cystoid variety, as the term implies, is characterized by the presence of one or more cysts, which usually arise from the occlusion of the openings of communication between the meshes of the cavernous variety and the efferent lymph vessels. Of the three divisions, the cavernous is the one usually met with.

The most common sites of lymphangioma are the neck, where it forms a certain proportion of the congenital cystic hygromas, the tongue, the lips, and the cheeks, in which it is known, respectively, as macroglossia, macrochilia, and macromelia, the groin, and the perineum. It has also been observed on the forehead, in the axilla, the mammary region, the shoulder, the buttocks, the penis, the adrenal, the kidney, the liver, and the mesentery. In all of these situations its point of departure is the superficial or deep connective tissue. The tumor may be diffused, as when it occurs in the tongue, the lips, or the cheeks, or it may be distinctly circumscribed, and even be surrounded by a well-formed capsule.

The etiology of lymphangioma is obscure. Although it may be acquired, and is occasionally ascribable to injury, it is nearly always congenital. Its growth is constant, but, as a rule, very gradual, so that many years may elapse before it attains the volume of a walnut. Now and then its increase is so very rapid that it may attain the size of a fist in six or eight weeks, or, in the course of fifteen or eighteen months, even of a child's head.

When it involves the tongue or the lip, the neoplasm is of a fibro-elastic consistence, but in other situations it is soft and compressible like myxoma, or even fluctuating, as when

it is of the cystoid variety. It is rarely painful, and it evinces no tendency to ulcerate; but it is liable to attacks of inflammation, during which it increases in volume, becomes hot, red, and tender, and gives rise to constitutional disturbance. The integument covering the growth is now and then the seat of small, transparent vesicles, which, on bursting, admit of the escape of its contents.

In the absence of lymphorrhœa and periodical attacks of inflammation, these tumors so closely resemble the soft fibromas, lipomas, myxomas, and simple angiomas, that their discrimination is most difficult before removal. The cavernous and cystic varieties may, however, be readily recognized by the exploring needle, the withdrawal of which is attended by the escape of colorless fluid presenting the chemical and physical properties of lymph.

Lymphangiomas are benign formations. The proper treatment is by excision; but the knife should be replaced by irritating injections when the cystoid variety is situated in the midst of important structures, as, for example, in the neck.

4. NEUROMATOUS TUMORS.

The nerves of animal life, especially the radial, ulnar, median, tibial, and peroneal, are subject to two forms of tumors, known, respectively, as the true and spurious neuroma, the former being composed principally of nerve substance, while the latter is seated on and in the nerve trunks, and includes fibromas, sarcomas, and myxomas, as well as the painful tubercle, incidentally noticed by Petit, Cheselden, Dupuytren, and other observers, and first accurately described, in 1812, by Mr. William Wood, of England. The neuromatous tumor, properly so termed, has been particularly studied and delineated by Mr. Robert W. Smith, of Dublin, who published a splendid monograph upon it in 1849.

A true neuroma may arise in the gray centres of the brain and spinal cord, but it is very uncommon in these situations, and is of no clinical importance. The form which chiefly interests the surgeon proceeds from the peripheral nerves, and is composed of nerve fibres, partly of new formation, and partly of preëxisting hypertrophied fibres, separated by connective tissue. It may contain medullated fibres, when it is denominated

Fig. 48.
Minute Structure of a True Neuroma seen
in Transverse Section.

Fig. 49.
Minute Structure of a True Neuroma seen in
Longitudinal Section.

myelinic by Virchow, or non-medullated fibres, when it is known as amyelinic neuroma; but the latter variety is difficult of determination, since it is scarcely possible to distinguish the fibres of Remak from fibrous tissue. Both sets of fibres generally exist in conjunction in the same tumor, as may be perceived by a reference to figs. 48 and 49, magnified 450 diameters, after Dr. Paul Bruns, of Tübingen. The former, copied from a transverse section of a plexiform neuroma of the posterior auricular region, shows the relation of the nerve fibres to their sheaths and to the interstitial connective tissue. In the largest fibres, the concentric arrangement of the myelin around the axis cylinder is very apparent, while it is missing in others. The smallest filaments are composed of naked axis cylinder alone. The latter figure represents a longitudinal section of the same tumor, with its double-contoured or myelinic nerves, and fibrillated and wavy connective tissue. In this particular specimen, therefore, the nervous substance constitutes the greater part of the growth; but other formations are met with in which the interstitial

tissue preponderates, thereby giving rise, in accordance with the nature of the latter, to the fibrous, glious, or myxomatous varieties of neuroma.

The neuromatous tumor is commonly solitary, but there may be a considerable number, varying in size from a pea to that of an almond, an egg, or even an adult head. It is solid to the touch, firm, inelastic, and of an oblong, ovoidal, or irregularly compressed form. When small, it has generally a distinct cyst, of fibrous structure, filled with a transparent jelly-like substance, and developed within the neurilemma of the affected nerve, the filaments of which are separated from each other, and spread out over the surface of the tumor. In cases of long standing, or when the tumor is of unusual bulk, the morbid mass is remarkably dense, white or nearly so, homogeneous, and destitute of a cyst, properly so called.

The neuromatous tumor occurs in both sexes, and at various periods of life, although it is most common in males and in middle age. Its progress is usually slow, and it seldom attains any great volume. The exciting causes are generally very obscure, but in some cases it is plainly traceable to the effects of external injury, as a wound, blow, or bruise; while in other instances there is a congenital or hereditary tendency to its formation. Now and then, a veritable neuromatous diathesis exists. In such an event, nearly all the nerves of the body, central, spinal, and sympathetic, may be affected. Smith, in one instance, counted as many as eight hundred enlargements, and in another upwards of two thousand. Occasionally it follows upon amputation, the nerves of the stump becoming enlarged and bulbous. The pain which attends the disease is very variable, both in degree and in character. In most cases it is neuralgic, exceedingly severe, sharp, darting, pungent, or stinging, and liable to periodical exacerbations, dependent, apparently, upon atmospheric vicissitudes, and disorder of the digestive functions. The slightest pressure, friction, or manipulation increases the suffering, which then, not unfrequently, amounts to great agony. The parts beyond the tumor, especially those supplied by the affected nerve, are cold, numb, and almost powerless. The pain is sometimes seated in the neighborhood of the tumor rather than in the tumor itself; and occasionally again there is no local distress whatever. Although the general health may remain good, ordinarily it is more or less impaired; and the system, constantly tortured by the excessive suffering, is gradually reduced to the utmost prostration.

Fig. 50.

Neuromatous Tumor with the Nerve passing to and from it.

The accompanying sketch, fig. 50, affords an excellent illustration of the gross characters of a myxomatous neuroma of the peroneal nerve. It had existed for nearly twenty years, during the last three of which it was exquisitely tender and painful. It was extirpated by Dr. Dalton and Dr. Hoffman, of Ohio, who kindly sent me the specimen. The operation was followed by sloughing of the fourth and fifth toes.

Under the term plexiform or cirsoid neuroma, Verneuil, Billroth, Bruns, and others, have described a peculiar form of this affection, which the last author, from whom the accompanying sketch, fig. 51, is taken, includes among the true neuromas. It consists of nodular, convoluted, or varicose cords, and may be mistaken for cirsoid aneurism, from which, however, it differs in its incompressibility and freedom from pulsation. It has been observed only in seventeen instances, in all of which it was congenital, and it appears to have a predilection for the subcutaneous connective tissue of the upper lid, and temporal and cervical regions. It is singularly free from pain, but is occasionally tender on firm pressure. The affection is generally attended with hypertrophy of the overlying integument and very marked enlargement of the sebaceous follicles.

The only effectual treatment is excision. As long, however, as the tumor is painless, or causes no inconvenience, it is best to let it alone. The operation is usually very sim-

ple, and devoid of danger. An attempt should generally be made to enucleate the tumor, by pushing aside the nervous filaments, or separating them from the parts in which they are embedded. When this is impracticable, from the manner in which the structures are fused together, the mass should be exposed by a free incision, and lifted out of its bed by

Fig. 51.

True Plexiform Neuroma.

dividing the affected nerve immediately above and below, over a grooved director. The loss of motion occasioned by this proceeding, even when it involves a comparatively large nerve, is usually restored in a very short time. Indeed, the chief inconvenience to which it gives rise is a sensation of coldness in the distal part of the limb, which may, however, remain for years. Amputation has been resorted to for the cure of this complaint; but it is difficult to conceive of a case in which it would really be necessary.

The painful *subcutaneous tubercle*, fig. 52, is generally situated, as the name implies, immediately beneath the skin, in the connective tissue, or in this tissue and in the skin.

Fig. 52.

Fig. 53.

Painful Subcutaneous Tubercle.
Microscopic Structure of the Subcutaneous Tubercle.

In its minute structure, as seen in fig. 53, it appears to belong to the connective tissue series, being composed of fibrous tissue either in a rudimental or perfect state. The pain which attends it would seem to establish some relation between it and the superficial nerves, and it is highly probable that amyelinic nerve fibres are involved in it. This point is, however, difficult of demonstration, as it is almost impossible to distinguish such fibres from those of fibrous tissue. In one instance, Virchow found that the tubercle was composed of gray nerve fibres. On being cut out it looks very much like a small mass of adipose substance, the section having a bright yellowish, grayish, or whitish aspect. Few vessels can be discerned in it. It is always remarkably small, seldom exceeding the volume of a pea; very movable; exquisitely tender to the touch; and the seat of frequent pain, often of a neuralgic character, and subject to constant exacerbations from the most trivial causes. It is generally represented as being most common in the lower extremities, but this does not accord with my experience, most of the cases that have come under my observation having occurred in the arm, forearm, and shoulder.

The painful tubercle is generally single, or, if multiple, more than two or three rarely exist in the same person. It occurs in both sexes, but much more frequently in women than in men, the reverse being the case in regard to the neuromatous tumor. Its development is usually tardy, and several years often elapse before it becomes very tender and painful. Women of a nervous, hysterical temperament appear to be most prone to its occurrence. During its development it always involves the skin.

The situation of this tumor just beneath the skin, or in the skin and connective tissue, the absence of discoloration of the surface, the peculiar character of the pain, the intolerance of manipulation, and the history of the case, generally suffice to determine the diagnosis.

The only remedy is free excision, including a small portion of the surrounding healthy integument. The disease never returns at the cicatrice, although it may occur afterwards in other parts of the body.

SECT. VI.—NEOPLASMS WHICH PROCEED FROM AND ARE COMPOSED ESSENTIALLY OF EPITHELIUM.

The epithelial neoplasms may be typical or atypical. The former embrace papilloma and adenoma, and the latter are confined to the carcinomatous formations.

1. PAPILLARY TUMORS.

The morbid growths comprised under this appellation have their physiological prototypes in the papillæ and villi of the cutaneous and mucous membranes from which they are generally derived; and they are composed, as is seen in fig. 54, from Rindfleisch, of vascular connective tissue, covered by epithelium, which varies in character in accordance with the origin of the formation. In some of these hyperplastic tumors, as in the ordinary wart, corn, and horn, the epithelial elements predominate; while, in others, as in the condylomas, and the villous or papillary growths of the mucous surfaces, the connective tissue forms the essential constituent.

Fig. 54.

Minute Structure of Papilloma.

Two varieties of papillomas naturally fall under this arrangement, the corneous or hard, and the mucous or soft: the former consisting of warts, corns, horns; and the latter of condylomas, certain outgrowths from the nose, larynx, the gastro-intestinal tract, the neck of the uterus, and the bladder, and the formations met with in the serous surface of the dura mater. The corneous variety is most common in the hands, fingers, toes, forehead, face, and trunk. The soft variety, on the other hand, is generally met with in the mucous canals, as the vagina, the rectum, and the nose. The excrescences which form around the anus and on the head of the penis, perineum, and vulva, as a consequence of inoculation with the venereal virus, belong to this category of morbid formations. The bladder, colon, rectum, and inside of the cheek, palate, and pharynx are occasionally the seat of villous growths, the papillary structure of which is generally recognizable by the naked eye. The very vascular, florid, sensitive tumor met with at the orifice of the female urethra, and the vascular excrescences occasionally seen in the interior of the larynx in and around the vocal cords, are well-marked examples of a similar kind. Certain tumors which occasionally project from the serous surface of the dura mater belong to the same group; and the researches of Professor Von Luschka into the minute structure of the Pacchionian bodies render it highly probable that these structures are merely enlarged villi which naturally exist upon the adherent surface of the arachnoid membrane.

Papillary tumors are frequently very vascular, and those of the mucous surfaces are not uncommonly attended with ulceration and exhausting hemorrhage. They are benign formations, but they may degenerate into carcinoma or sarcoma. Concerning their treat-

ment, no definite plan need be laid down here, as the subject will be fully discussed in connection with the different organs and structures in which they are developed.

2. ADENOMATOUS TUMORS.

The glandular tumor, or adenoma, owes its name to the peculiarity of its structure, which is a close imitation of the normal glandular tissue, whether acinous or tubular. It is essentially a hyperplastic growth, consisting of newly-formed gland tissue, corresponding in its main features with what Lebert has described under the name of "partial glandular hypertrophy," and is frequently, but incorrectly, described as adenoid tumor. Its principal seats are the parotid, thyroid, mammary, prostate, and sweat glands, and the mucous follicles of the lip, cheek, palate, nose, vulva, vagina, uterus, and rectum. In the breast the new product is either imbedded in the substance of the organ, or it projects from its surface as a peripheral outgrowth, continuous with the parent tissues by a distinct pedicle. In adenomas of the parotid and prostate glands a similar law obtains in regard to the site of the new growth.

An adenoma is, for the most part, a solitary tumor, of a firm, dense, inelastic consistence, especially in its earlier stages, of a whitish, grayish, or pale straw color, surrounded by a capsule, or limitary membrane, easily enucleated, and seldom larger than a hickory-nut, an almond, or a pullet's egg. The sectional surface has often a glistening appearance, and, in recent growths, yields no fluid on pressure. Few bloodvessels enter into this tumor. The epithelial cells which naturally line the ducts and acini of the glands commonly consist of a single layer.

Under the microscope the newly-formed glands are arranged as acini, or as tubes, as in fig. 55, from Green, separated usually by a small amount of connective tissue. The cells which line the lobules or ducts rest upon a limiting membrane, which serves to distinguish the growth from carcinoma. The best type of the acinous or lobular adenoma is that which occurs in the mammary gland. The tubular or duct adenoma proceeds from the mucous membranes, and frequently constitutes one of the varieties of mucous polyp.

In the mucous follicles, the tumor, rarely larger than a cherry, or small nut, is always, as in the mammary and prostate glands, distinctly encapsulated, while in the thyroid body, belonging to the ductless order of glands, the new glandular structure, usually even in its earlier stages, exhibits a remarkable tendency to cystic

Fig. 55.

Minute Structure of Adenoma of the Mamma.

transformation, so characteristic of goitre. All adenomas exhibit, indeed, the same tendency, which is due to mucoid softening of the proliferating epithelial cells and dilatation of the ducts. In some cases, the epithelium gives rise to vegetations or papillæ which more or less completely fill the cysts.

The period of life at which adenoma is developed varies in the different organs. In the breast it is most frequent from the age of puberty to that of thirty-five, young prolific females being its most common subjects. In the thyroid body it generally begins before the fifteenth year, especially in those parts of the world in which goitre is endemic. In the labial, buccal, vaginal, and uterine glands the occurrence is most frequent in young and middle-aged persons. In the prostate gland it is usually associated with, or a consequence of, senile hypertrophy of that organ, occurring either in its substance, or as a pedunculated, polypoid outgrowth.

In the mammary gland adenoma is frequently quite tender on pressure, and occasionally even very painful, especially in young females, the subjects of dysmenorrhœa, the suffer-

ing being then very liable to assume a neuralgic character. In most of the other organs the tumor incommodes simply by its bulk and situation, or mechanical inconvenience.

Adenoma usually arises without any assignable cause. Its progress is generally very slow, and it seldom attains any considerable volume, although when it invades an entire gland, as the mammary or parotid, it may reach a great bulk. In its character the tumor is essentially benign, but, in exceptional cases, it is no doubt, like other benign growths, capable of assuming malignancy. When thoroughly extirpated, no relapse will be likely to occur, although examples have been recorded in which as many as three, four, and even five operations were performed upon the same tumor.

Adenoma is distinguished by its locality, by its tardy and equable growth, by its circumscribed, ovoid, and bossed outline, by its firm, inelastic consistence, by its hard and heavy feel, by the absence of lymphatic involvement, and by the integrity of the general health.

In the treatment of adenomas very little is to be expected from medication, and a spontaneous cure is very uncommon. Occasionally, under favorable circumstances, dilute tincture of iodine and a weak ointment of the biniodide of mercury prove useful in promoting the absorption of the tumor. Iodide of potassium and bichloride of mercury administered internally, have sometimes been beneficial. The efficacy of such treatment is most evident in cases of recent standing and in growths of small size. Some surgeons speak favorably of methodical compression, but as this is difficult, and in many cases impossible, little advantage is to be anticipated from its employment. When the tumor is painful, as when it is the seat of neuralgia, or of large size, causing inconvenience by its weight or pressure, or when it is partially softened, the only rational remedy is extirpation. A single incision often suffices to expose the tumor and to effect its enucleation. The whole organ in which it is situated must be sacrificed when the disease pervades its entire substance; but such a procedure, for reasons previously mentioned, will seldom be necessary.

3. CARCINOMATOUS TUMORS.

Under the term carcinomatous are comprised certain morbid growths, which have the effect, within a variable period after their formation, of destroying not only the tissues in which they are located, but also the life of the patient. The formations commonly embraced under the present head are scirrhus, encephaloid, colloid, melanosis, and epithelioma. It would greatly simplify the study of these affections if the term " cancer," by which some of them continue to be designated, were altogether discarded from surgical nomenclature. This expression, introduced in the infancy of the science, is commonly employed as the substantial equivalent of malignant, and is, therefore, calculated to mislead the mind of the inquirer.

Of the extensive prevalence of carcinomatous disease some idea may be formed when it is stated that, in the five years from 1838 to 1842, inclusive, 11,662 persons died of it in England alone, independently of the cases which occurred in London. Of these cases, 8746 occurred among women, and 2916 among men, or in the ratio almost of three to one. Mr. S. W. Sibley, in 1869, analyzed 522 cases of carcinoma, collected from the records of the Middlesex Hospital, of which 419 related to females, and 103 to males. This disparity of the disease in the two sexes is due to the extraordinary frequency of carcinoma of the uterus and mamma, particularly the former, which suffers nearly as often as all the other organs together.

These various morbid formations, although widely differing in many of their characters, possess certain features in common with each other, which may be briefly enumerated before they are individually described.

1st. Microscopically considered, they are distinguished from all other neoplasms by the marked alveolar structure of their fibrous stroma, the alveoli being disorderly crowded with unadherent polymorphous cells of an epithelial type, without the intervention of formed intercellular substance.

2dly. They are always derived primarily from the epithelium of the glands, or of the skin, and mucous membranes. Instead of being confined by a limiting membrane, as occurs, for example, in adenoma of the mamma, the epithelial cells infiltrate, grow, or thrust themselves into the surrounding connective tissue, thereby giving rise to an atypical epithelial formation, or one which is entirely unlike the normal glandular structures.

3dly. They are all at the outset of a purely local character, but after a variable period of their existence they evince malignant attributes, as is indicated by their infiltrating the

adjoining tissues, by the production of similar tumors in the associated lymphatic glands, and by the formation of metastatic deposits in the various textures and organs.

4thly. They occur only, as primary affections, in the epithelial organs and tissues of the body, particularly during middle age, in persons of all temperaments, occupations, and social conditions. They occasionally display a marked hereditary tendency, and also a disposition to appear in several members of the same family.

5thly. Their progress is generally rapid, most of them causing death in from nine months to two years and a half from their commencement.

The so-called cancer cells, which, along with the creamy, homogeneous, or granular intercellular substance, form what is termed the cancer-juice, have been, and still are, a prolific source of disputation. Apart from the peculiar arrangement of the stroma, these protoplasms cannot be said to be characteristic of carcinoma, and yet the practised microscopist would not hesitate to pronounce a tumor to be of that nature, if it were composed principally or entirely of such nucleated cells as are delineated in fig. 56, from Green, Rindfleisch, and Paget, representing typical forms derived from different carcinomatous formations. At *a* are exhibited the multiform cells of scirrhus and encephaloid, which

Fig. 56.
Cells of Carcinoma.

range from $\frac{1}{1500}$ to $\frac{1}{700}$ of an inch in diameter. In shape they vary greatly. Commonly oval or nearly spherical, some are pyriform, some fusiform, some angular, others reniform, and they are provided with one, and occasionally even with several large, oval, well-defined, eccentric, nucleolated nuclei. At *b* are represented the most common types of cells of epithelioma. They are generally round-oval, singly nucleated, flattened, and scale-like, and vary from $\frac{1}{1200}$ to $\frac{1}{200}$ of an inch in their chief diameter. At *c* are delineated the cells of colloid carcinoma, which consist of the vacuolated and the seal-ring forms, from $\frac{1}{500}$ to $\frac{1}{250}$ of an inch in diameter. The origin of the so-called cancer cells, the distinctive feature of which is their epithelial character, is still involved in mystery. According to Virchow, Rindfleisch, Volkmann, Cornil and Ranvier, Tripier, Coyne, and Moxon, they are developed by proliferation of the connective tissue corpuscles, a theory of formation which has been placed in doubt by the results of embryological inquiry. His, Aeby, Thiersch, Waldeyer, Billroth, Samuel, Klebs, Lücke, Langhans, and other pathologists, contend that histological researches have failed to demonstrate the derivation of the epithelial cells from corpuscles of connective tissue. Thiersch maintains that epithelioma originates from increase and multiplication of preëxisting epithelial cells alone; while Waldeyer and Billroth extend this view to all carcinomas. That epithelium must be produced from its like, and that carcinoma can only arise as a primary growth in the epithelial structures which are derived from the outer and inner layer of the embryo, are statements which I fully indorse, and I believe that the continuous proliferation and transplantation of the epithelium are sufficient to account for all the changes met with in the development and extension of carcinoma, without invoking the aid of other theories.

The stroma, or basement structure, the second essential constituent of carcinoma, consists of succulent, preëxisting connective or fibrous tissue, although it is, now and then, partly a new formation. The trabeculæ of the stroma form elongated ovoidal spaces or meshes, which freely communicate with each other, and impart to it an alveolar or cavernous appearance. The cells are packed in the alveoli, and a few lymphoid cells are usually intercalated between the fibres of the stroma itself. These appearances are well shown in fig. 57, from Rindfleisch, which exhibits a partially pencilled-out section of encephaloid, magnified 300 diameters. The stroma is variously supplied, according to the variety of the neoplasm, with bloodvessels, some of which are normal to the part,

while others are of new formation. Lymphatic vessels have been demonstrated to com-
municate with, or to open into, the alveoli, as in fig. 58, from Cornil and Ranvier, a fact
which explains the almost constant involvement of the lymphatic glands.

Carcinoma is always derived from the epithelial elements of the glands, or of the
skin and mucous membranes. Its evolution
in a glandular organ, as the mamma, can be
readily traced. Thus, the acini and ducts be-
come enlarged and deformed, and more or less
completely filled with proliferating epithelium.
The periglandular connective tissue is, at the
same time, infiltrated with lymphoid cells, out of
which the newly formed stroma is produced. Dur-
ing the second stage, the basement or limiting
membrane of the acini and ducts is broken
through, and the cells extend into the new con-
nective tissue and the preëxisting lymph spaces
as solid, branching cylinders, or plugs, whereby
the normal appearance of the mamma is com-
pletely destroyed. Some of these changes, as
well as the relation borne by the cells to the
stroma, are represented in the adjoining sketch,
fig. 59, from Rindfleisch, magnified 300 diame-
ters. At *a* the connective tissue is infiltrated
with corpuscles, the nuclei of which at first di-
vide, followed by fission of the cells and their accu-

Fig. 57.

Stroma of Carcinoma.

mulation in rows.   The young cells finally enlarge and assume various shapes, until, as
depicted at *b*, they have collected in groups in the meshes of the tissue, the fibres and
lymph spaces of which they have disparted to form elongated ovoidal spaces or alveoli.

Carcinomatous tumors are at the outset local degenerations of the tissues or organs in
which they are situated.   The marked tendency to recurrence after extirpation, to con-
tamination of the lymphatic
glands, and to the development
of secondary nodules in the
viscera, so far from being a
sign of a constitutional taint
or dyscrasia, merely shows that
the original tumor acts as a
focus of infection of adjacent
and distant parts. As they are
not surrounded by a capsule,
their growth is generally rapid,
and the increase in volume is,
for the most part, peripheral,
their constant tendency being
to infiltrate the surrounding
structures by the penetration
of young epithelial cells into
the continuous, loose connec-
tive tissue spaces. This very
interesting fact has a direct
and most important bearing
upon the results of surgical
operations performed for the
removal of malignant forma-
tions.   Schroeder Van der
Kolk, to whose researches we

Fig 58.

trate of silver. *c*. Lymphatics showing silver staining of the endothelium.

are mainly indebted for this knowledge, states that the tissues immediately around the
morbid mass, although perfectly healthy in appearance when viewed with the naked eye,
are, if examined with the microscope, found to be infiltrated with young cells, which
gradually increase in size and number in proportion as the periphery of the tumor is ap-
proached. This fact affords a ready reason why carcinomatous growths so frequently
recur after extirpation at the site of the original disease. Fig. 60, from Billroth, magni-

fied 350 diameters, and representing cell infiltration of the fatty tissues around a carcinomatous lymphatic gland, serves to convey a good idea of these appearances.

A characteristic feature of carcinomatous growths consists in their tendency to multiply

Fig. 59.
Scheme of Development of, and Retrograde changes in, Carcinoma.

and disseminate themselves, until, in many cases, a considerable number of tissues and organs are successively affected with analogous deposits. This infecting power is due to the transference of germs or juices by the veins or lymphatics, particularly the latter, as is evinced by the early and frequent invasion of the lymphatic glands and the blocking up of the vessels themselves with carcinomatous material. It is very rare to witness secondary nodules in distant organs without involvement of the intervening glands, and in this respect carcinoma, as has already been pointed out, bears a striking contrast to sarcoma.

It would be of great practical utility if we knew the origin of carcinoma, or the causes, local and constitutional, under the influence of which it is developed; but upon this subject we are, unfortunately, entirely ignorant, nor is it likely that our inquiries concerning it will lead to a satisfactory solution of a question which has occupied so much attention.

Fig. 60.

Cellular Infiltration of the Fatty Tissues around a Carcinomatous Lymphatic Gland.

Among the predisposing causes may be mentioned age and sex. Carcinoma never occurs before puberty, and is most common between forty and sixty, or during the period of functional decline of the various secreting organs. It is far more prevalent in females than in males in consequence of the extraordinary frequency of its occurrence in the uterus and mammary gland, but its evolution does not appear to be influenced by pregnancy or lactation. It is sometimes inherited; that is, it manifests a tendency to descend from parent to child; and this factor in its production is due to the transmission of a peculiarity of tissues, which renders them more prone to take on carcinomatous degeneration in some persons than in others not similarly predisposed. This tendency, however, is much less frequent than is generally supposed, since of 389 examples of carcinoma of the female breast, analyzed by Dr. S. W. Gross, only 10.30 per cent. could be assigned to hereditary influence. Besides, it should be remembered that there is a difference, and that a very wide one, between the transmissibility of this disease from the parent to the offspring, and its coexistence, or successive development, in different members of the
same family. The latter occurrence, although also very uncommon, is much more frequent than the former, of which my own experience has supplied me only with a few examples. Lately, I saw a well-marked carcinoma of the mammary gland in a lady whose mother and maternal aunt had died of a similar disease. In 1855, I prescribed for an aged female with a carcinoma of the lip, whose mother had perished from carcinoma of the breast, and the father from carcinoma of the tongue. One of the most remarkable and instructive instance of this kind upon record, is that related by Dr. Warren, in his work on Tumors. A man died of carcinoma of the lip; his son had a similar disease in the breast, from which, after having undergone an operation at the age of sixty, he finally lost his life. Two of his sisters had carcinoma of the mammary gland; they were operated upon, but ultimately died from a relapse of the malady. A daughter of one of the ladies had a carcinoma of the breast, which was removed at an early period; she recovered, but perished some years after, from disease of the uterus. A daughter of the gentleman had a carcinoma of the breast, and there was reason to believe that other members of the family were affected by the same malady.

A case, almost equally remarkable, of this hereditary tendency to carcinoma, was communicated to me by the late Dr. J. M. Warren. In this instance, a man who died of carcinoma of the penis, had lost his father, grandfather, and great-grandfather from similar disease. In a case, recorded by Broca, out of a family of twenty-six, in three successive generations, fifteen died of carcinoma.

More frequently, as has already been stated, the disease occurs, either simultaneously or successively, in several members of the same family. My own practice has afforded me a number of instances of this kind, and all writers on carcinoma narrate examples of it. In one remarkable case, four out of six members of one family have died of the disease; one from carcinoma of the uterus; another from carcinoma of the mammary gland; a third from a malignant polyp of the nose; and the fourth from carcinoma of the thoracic viscera. Professor Gibson gives an instance of carcinoma of the breast in four sisters. Of 322 cases of carcinoma, analyzed by Paget, the disease occurred in other members of the family in 78, or very nearly in one-fourth. In 305 cases collected from the records of the Middlesex Hospital, London, by Mr. S. W. Sibley, the disease was traced to the relatives of the patients in $8\frac{3}{4}$ per cent. of the entire number of cases. Most of these cases occurred in females.

The opinion, once so prevalent, that carcinomatous affections owe their origin to a peculiar virus, either generated within the system, or introduced from without, has long been obsolete. It is, at all events, perfectly certain that if there be such a poison, its existence has never been demonstrated. The juice of carcinoma, even when the disease is in a state of ulceration, is not inoculable, or communicable by immediate contact, as the matter of smallpox, vaccinia, chancre, or gonorrhœa. If it were, the disease would often spread indefinitely over patients affected with it, from mere contact with the discharges; nurses would become infected from handling the dressings, and surgeons would not be safe in performing any operations; and yet there is not upon record a solitary instance, of a reliable character, from the earliest periods of the profession down to the present time, in which the malady was imparted in this manner. Carcinoma of the penis has never been transmitted during coition. Carcinoma may, however, be inoculated by injecting the juice of infected animals into the veins or tissues of sound animals; and small fragments of carcinoma removed from man have been successfully transplanted in animals.

Of the direct exciting causes of carcinoma the most frequent are injury and chronic inflammatory or irritative processes. Thus, epithelioma of the lip may be caused by jagged teeth, or smoking foul clay pipes; epithelioma of the tongue may result from icthyosis of that organ; psoriasis and eczema of the nipple are occasional precursors of carcinoma of the mamma; epithelioma of the penis is frequently traceable to phimosis; and carcinoma of the uterus and stomach is notoriously the outcome of catarrhal inflammation of those organs. The incompatibility of carcinoma and tubercle, in a state of active growth, is well established. There are, of course, exceptional cases, but they are very uncommon; and yet it not unfrequently happens that the relatives of persons affected with carcinoma die of phthisis. When active phthisis exists in a patient affected with carcinoma, the former malady may so completely obtain the ascendency over the latter as to cause the morbid growth to shrink and wither. Organic affections of the kidneys, liver, bones, skin, nerves, and bloodvessels neither prevent the occurrence of carcinomatous disease nor materially alter its course after its development. The absence of organic degeneration of the heart in those who die of carcinoma has been placed in a very clear light by the observations of Mr. Sibley and Mr. Moore, of the Middlesex Hospital, London, an institution largely devoted to the treatment of this class of subjects.

After carcinoma has made considerable progress, it impresses itself upon the constitution, as is indicated by the worn and haggard features, the sallow complexion, and the emaciated and exsanguineous condition of the system, characters which it is impossible to mistake. The countenance bears the impress of the disease, looking as if it had been stamped with the seal of malignity.

The so-called cancerous cachexia is present chiefly in carcinoma attended with serious involvement of the nutritive functions and imperfect sanguification. In external carcinoma it is frequently entirely absent until internal complications arise, or until the system has been weakened by profuse discharges, or repeated hemorrhages. In carcinoma of the liver, stomach, and other important organs, on the contrary, cachexia often occurs at an early stage of the disease. It generally manifests itself in its worst forms in encephaloid. Its principal characteristics are a sallow, shrunken condition of the features ; a soft, flabby state of the muscles ; rapid absorption of the fat ; and an impoverished condition of the blood, accompanied with abnormal frequency of pulse, night sweats, and general debility.

The immediate causes of death in carcinomatous diseases are various. Most commonly life is worn out by anemia, inanition, and hectic irritation. In many cases the vital powers are seriously undermined, if not completely exhausted, by the violence of the hemorrhage, after the establishment of ulceration. The excessive fetor, the copious ichorous discharges, and the severity and constancy of the pain, always greatly expedite the downward tendency. Sometimes carcinoma destroys life by mechanically impeding the functions of an organ, as when the disease affects the œsophagus, stomach, or bowel. In open carcinoma, attended with a profuse secretion of ichorous, sanious, or sanguinolent matter, death may be occasioned by septicemia, from the absorption of some of the unhealthy fluid into the system.

A spontaneous cure of carcinoma, in any of its forms, is an extremely rare occurrence. Of the causes which may give rise to it, the most frequent is inflammation, followed by gangrene, by which the morbid mass is sometimes lifted bodily out of its natural bed, as neatly, in fact, as if it had been removed with the knife. Rokitansky speaks of the saponification of carcinoma—a conversion of its protein-compounds into fat—as one of the modes of cure, especially of encephaloid ; and he also imagines that such an event may be brought about by the gradual condensation of the stroma of these growths, thus depriving their cells of proper nourishment. The shrunken, shrivelled appearance occasionally seen in scirrhus of the breast of very elderly females, is probably, in great measure, if not solely, due to this circumstance.

Carcinomatous tumors, like other neoplasms, are liable to undergo inflammation and various transformations. Inflammation, softening, and consequent ulceration, are not uncommon, particularly in the advanced stage of the growth. The ulcer shows no disposition to heal, and new carcinomatous nodules are constantly being formed around it, which go through similar changes. Fatty metamorphosis of the cells occurs in all the varieties of carcinoma, and is never entirely absent. It sometimes proceeds to such an extent that the fibrous stroma contracts and shrinks, and the alveoli contain only a few cells and granular debris. This cicatricial tendency is met with in scirrhus, giving rise to what is known as withering or atrophying scirrhus. These retrograde changes are represented at *c* and *d*, fig. 60. The calcareous degeneration has occasionally been noticed in epithelioma and scirrhus. Pigmentation and colloid transformation of the cells, and mucoid degeneration of the stroma are also met with.

The histological varieties of carcinoma are determined by structural peculiarities, or by the relative proportion of the stroma and cells, by the type of the cells, and by certain degenerations and transformations. The clinical divisions are scirrhus, encephaloid, colloid, melanosis, and epithelioma. Of these, scirrhus, fibrous, hard, or chronic carcinoma, is composed of small cells, and a relatively large amount of firm, contractile fibrous tissue. Encephaloid, medullary, soft, or acute carcinoma is characterized by the large size of its cells, and the small proportion of delicate stroma. Colloid or gelatinous carcinoma differs from the preceding varieties only in the fact that the protoplasm of its cells has undergone colloid degeneration. Melanotic or pigmented carcinoma is distinguished by the fact that its cells are infiltrated with granules of melanin. Epithelioma, or epithelial carcinoma, is the variety in which the cells are analogous to those of squamous epithelium ; and it differs from the other varieties in always proceeding from a mucous or cutaneous surface.

1. SCIRRHUS.

Scirrhus, so called on account of its great density and firmness, is rare until after the age of forty, when it is sufficiently common. The period of its greatest frequency is

from the forty-fifth to the fifty-fifth year. Women suffer much oftener than men, but in what proportion has not been ascertained. The influence of habit, temperament, and occupation upon the production of the disease is also undetermined. Of the exciting causes of the disease also very little is known. It generally arises spontaneously, and makes perhaps considerable progress before any suspicion is aroused as to its true character. Occasionally, although seldom, its development is manifestly due to the influence of some external injury, as a blow, fall, or bruise ; and it is not unfrequently the result of catarrhal inflammation, as when it occurs in the mucous surfaces.

Certain organs are more prone to scirrhus than others. Thus the mamma, the pylorus, the rectum, the œsophagus, and uterus are particularly liable to suffer, and it is occasionally met with in the skin, vagina, and jaws. The testicle is singularly exempt from it.

Scirrhus appears under several varieties of form, as the tuberoid, stratiform, and infiltrated, of which the first is the one, surgically speaking, of the greatest interest. The other two occur chiefly in the internal organs, particularly the œsophagus, stomach, colon, and rectum, the submucous connective tissue of which they often so completely transform as not to leave a vestige of the original structure, at the same time that they encroach very seriously, if not fatally, upon the caliber of the tube. The affected part, dense and crisp, cuts almost like fibrous cartilage, and is of a pale yellowish or grayish hue, with white fibrinous intersections. The stratiform variety is occasionally met with in the skin, but the occurrence is uncommon. Scirrhus of the uterus generally presents itself as an infiltration.

The best example of the tuberoid variety occurs in the mamma. Sometimes the tumor consists of one single mass, but more generally it is made up of several, which together may form a growth as large as an orange, or even of a fist, hard, dense, inelastic, and almost incompressible, grating under the knife, of variable shape, but generally globular or ovoidal, movable with, and deeply inlaid in the tissues among which it is situated. The fibrous intersections which pervade the interior of the morbid mass are generally of a dense, firm consistence, and of a grayish, bluish, or rosaceous color. It is questionable whether the fibrous bands, as they are commonly called, are ever entirely of new formation.

A section of a scirrhous tumor, especially in its more matured stages, exhibits a whitish, homogeneous aspect, and yields, upon being scraped, a peculiar fluid, sometimes of a whitish, creamy hue, but more generally of a pale, grayish, turbid appearance, not unlike thick gruel, which contains great numbers of cells, and is known as the cancer juice. It is slightly unctuous to the touch, readily mixes with water, and often contains a considerable quantity of free oil. It exists very sparingly in recent specimens, and is evidently caused by the softening and disintegration of the mass, preparatory to ulceration.

Scirrhus has a very feeble circulation, its vessels being remarkably small, and probably wholly derived from the surrounding parts. The paucity of vessels affords a satisfactory clue to the slow growth, and comparatively small size of the morbid product, and a reason, also, why there is so seldom any considerable hemorrhage after ulceration.

Scirrhus is composed, as is represented in fig. 61, from Arnott, of a stroma of dense, inelastic, fibrous tissue, arranged so as to form alveoli, in which comparatively small and

Fig. 61.

multiform epithelial cells are contained. In the withering or atrophying variety the alveoli are merely represented by a few elongated or fusiform clefts, which contain fatty detritus, or one or more rows of unchanged cells.

The progress of this disease is generally more slow than that of the other carcinomatous growths, both as it respects its tendency to ulceration and to the destruction of life. It is seldom that a scirrhous tumor of the breast becomes an open sore under nine, twelve, fifteen, or eighteen months ; not unfrequently, indeed, several years elapse before it takes on this kind of action. In 1857, I had at my Clinic an elderly lady, once a patient of Sir Astley Cooper, in whom the disease had existed for more than twenty years before there was any disposition to ulceration. Several other cases of somewhat less duration have been under my observation. In general, however, the tendency to ulceration shows itself towards the end of the first or the second year, commencing usually in a superficial portion of the tumor, sometimes at one, and at other times at several points, the process being preceded and accompanied by more or less discoloration of the surface, and by the adhesion of the skin to the subjacent structures. The color is always dark, purple, or

Minute Structure of Scirrhus.

livid, the vessels immediately concerned in its production being enlarged and deeply congested, frequently presenting an appearance as if they were inlaid in the cutaneous tissues. The part at length giving way, an unsightly ulcer is exposed, having hard, steep, rounded edges, and a foul-looking bottom, generally incrusted with spoiled lymph. The discharge is always sanious, ichorous, or sanguinolent, more or less fetid, irritating, and often remarkably profuse. It tarnishes silver, imparts a green color to syrup of violets, and, on admixture with sulphuric acid, evolves a peculiar gas, having many of the properties of sulphuretted hydrogen. No healthy granulations ever form upon such an ulcer; hence it never heals, the plastic matter which it secretes being always speedily devitalized. There are, of course, exceptions to this rule; but they are very uncommon, and I have met with very few. Sometimes the scirrhous ulcer has a remarkably excavated appearance, as if it had been dug out with a punch. The parts immediately round the ulcer are always very hard, tender, discolored, and œdematous.

Another tendency of the scirrhous tumor is to contract adhesions to the structures in and among which it is situated. This disposition, which often manifests itself at a comparatively early period, is always very conspicuous during the later stages of the malady. The immediate cause of the adhesions is the extension or growth of the epithelial cells into the skin, connective tissue, muscles, glands, and even bones, involving all in one common mass.

A tumor of this kind not only affects the parts with which it lies in more immediate contact, but it often extends its influence to others farther off. The structures that are most liable to suffer in this way are the lymphatic glands, which frequently take on the same kind of action, becoming enlarged and indurated, and exhibiting, on section, precisely the same appearances as the original tumor. Sometimes, again, parts still more remote become involved in the morbid action. Thus, in scirrhus of the mamma there is often not only great contamination of the axillary lymphatic glands, but serious swelling of the corresponding arm, either from an extension of the primitive affection, or from obstacle to the return of the blood in the veins.

Thus the tendency of this disease is to spread and to contaminate the surrounding structures, making itself deeply felt not only locally, but constitutionally. In exceptional cases, the morbid influence is closely circumscribed, limited, perhaps for years, to the spot in which it originally appeared; even then, however, it eventually breaks through its barriers, and spreads among the adjoining tissues. Finally, after having remained in the part for a time, nature occasionally makes an effort at extrusion, the tumor being invaded by gangrene, and at length cast off as a slough. Such an occurrence, however, is extremely rare, and I have witnessed only one instance of it. The patient, an elderly lady, fat, and otherwise healthy, had had a medium-sized scirrhous tumor in one of the mammary glands for several years. Suddenly, without any assignable cause, inflammation set in, and in a few weeks the whole mass was lifted from its bed as neatly as if it had been done with the scalpel. Some time afterwards the disease broke out in the axillary lymphatic glands, and made rapid strides towards a fatal termination.

The symptoms of scirrhus necessarily resolve themselves into local and constitutional. The former can only be satisfactorily studied as they appear in an external tumor, as, for example, the mamma. In taking hold of such a growth, one is struck with its extraordinary hardness and density; it is firm, incompressible, and inelastic. If it be of recent origin, it will be found to be perfectly circumscribed and movable, the examiner being able to grasp it with the fingers, and to push it about beneath the skin; at a later period, however, it contracts adhesions to the surrounding parts, and becomes more or less firmly fixed in its situation. The morbid product may occur as a solitary tumor, or several little lumps may appear simultaneously or successively, and, gradually coalescing, a mass of considerable size may thus be formed.

The pain of scirrhus is peculiar. It is sharp, lancinating, or stabbing, darting through the parts like an electric spark, or causing a sensation as if needles were thrust into them. It makes its appearance at an early date, gradually increasing in severity, and becoming at length a source of intense suffering. It may be steady and persistent, but more commonly it is intermittent. It is always aggravated by damp states of the atmosphere, by derangement of the digestive organs, and by whatever has a tendency to impair the general health. In some cases it is of a neuralgic character, and then, instead of being limited to the morbid mass, it often shoots about in different directions among the neighboring structures. During the later stages of the disease it is usually so constant and violent as to deprive the patient of appetite and sleep, thus rapidly urging on the fatal issue.

As the disease advances, the skin is gradually tied down to the morbid mass, and soon becomes hard and livid, its vessels being at the same time very much enlarged and congested. Eventually erosive action sets in, and thus a steep, excavated ulcer is formed, the seat of a foul, ichorous discharge, and incapable of furnishing healthy granulations, or laudable pus, or of undergoing repair. The tumor is now firmly adherent to the surrounding structures, and there is generally, although not invariably, lymphatic involvement. The ulcer sometimes bleeds, but seldom more than a few drachms, or, at most, a few ounces. The flow may be purely capillary, or it may proceed from a tolerably large vessel, arterial or venous, laid open by the morbid action, and unable to retract in consequence of the condensed condition of the circumjacent tissues.

Scirrhus occasionally assumes an atrophic form, causing more or less wasting of the affected organ, and a consequent reduction of its natural size. This form of carcinoma is almost peculiar to the mammary gland of elderly females, after the age of sixty, in whom the disease sometimes remains stationary for a number of years, the morbid growth being characterized by extraordinary hardness, with little, if any tendency, to ulceration and constitutional involvement. On the other hand, a tumor of this kind sometimes attains an unusual bulk, caused by the infiltration of the normal tissues by the carcinomatous matter, the resulting mass being of a dense, compact structure, freely interspersed with fatty and fibrous substance, in an altered condition. In what is called acute scirrhus, the disease advances with extraordinary rapidity, the case often terminating fatally within a few months of its first appearance, from extensive constitutional implication.

Scirrhus, in its earlier stages, produces little or no constitutional disturbance. It is strictly a local affection, annoying and fretting the parts directly involved in it, but not awakening any general sympathies. A little mental disquietude, the result of the consciousness that there is a suspicious tumor or lump, is the only thing that excites attention. By and by, however, the health begins to fail; the appetite is impaired; the sleep is interrupted by the severity and frequency of the pain; the secretions are sadly disordered; the bowels are irregular; the assimilative functions suffer; occasional attacks of fever take place; the flesh and strength gradually decline; the mind is depressed; and life is beset on every side by the treacherous and unrelenting foe. During the latter stages of the malady, sometimes even before there is any serious lymphatic involvement, the countenance assumes a peculiar sallow, cadaverous expression, so denotive of the carcinomatous cachexia; diarrhœa and sweats set in; the limbs become anasarcous; and at length the patient dies utterly exhausted, being literally fretted to death by the disease.

During the progress of this malady secondary scirrhous deposits often appear in other parts of the body especially the liver, lungs, and pleura; the blood is thin and colorless; and the solids are pale, flabby, and wasted. Even the bones often experience important changes, particularly those of the extremities, which are sometimes rendered so fragile as to give way from the slightest cause. Many years ago I had under my charge, on account of scirrhus of the mamma, a lady of seventy-three, who broke her right femur a few days before she died, simply by turning over in bed.

2. ENCEPHALOID.

Encephaloid has various synonyms, of which the most common are soft, acute, medullary, and cerebriform carcinoma, and fungus hematodes. All these various appellations have reference either to the appearance, consistence, or progress of the morbid product, and are, therefore, more or less appropriate. That of encephaloid, however, is, on the whole, the least objectionable, and is the only one that ought to be retained.

Encephaloid generally comes on spontaneously, although, now and then, it is directly traceable to the effects of external injury, as I have witnessed in a number of instances. Thus, in 1861, I attended a medical gentleman, sixty-eight years of age, on account of an encephaloid tumor of the maxillary sinus, the result of an accidental blow received several months previously. A young man hurt his testicle in riding on horseback. The organ soon began to increase in bulk, the lymphatic glands of the groin became involved, and in less than six months death occurred from soft carcinoma. In both of these cases the disease was of unusually rapid development, and, such, I believe, will generally be found to be the fact when it is caused by violence.

The affection is most common in the liver, kidney, ovary, testicle, mamma, prostate, and salivary glands. Both sexes are liable to it, but the greatest number of cases occur in females between the fortieth and sixtieth years. Encephaloid carcinoma, like scirrhus, consists of an alveolar stroma with inclosed epithelial cells; but it differs from the latter

growth in that the stroma is more delicate and the cells are more numerous and of larger dimensions, as is well represented in fig. 62, from Green.

Fig. 62.

In regard to its arrangement, encephaloid occurs under three varieties of form, as a tumor, a stratum, and an infiltration, the first being the most common, and surgically considered the only one of any particular interest. It varies in volume from a pea to that of an adult's head, its shape being generally somewhat ovoidal, and its surface more or less lobulated.

On section an encephaloid tumor presents a white or grayish pulpy appearance like that of the fœtal brain. In not a few specimens the grayish-white basis is mottled with pink, red, or brown areas, which are indicative of increased vascularity, and slight effusions of

Minute Structure of Encephaloid.

blood. When the tissue resembles a recent coagulum, or contains spaces filled with blood, the tumor is termed hematoid or telangiectatic carcinoma, which is synonymous with fungus hematodes. This variety of tumor is met with principally in the mamma, the testicle, and the ovary.

Encephaloid, being an extremely vascular structure, is endowed with a high degree of vitality, growing generally with great rapidity, and often attaining a very extraordinary bulk within a few months from its first appearance. Its vessels, which are unusually large, are arranged in a close, intricate, and retiform manner, and its circulation is always remarkably active, thus strikingly contrasting with that of scirrhus, and affording a ready explanation of the differences in the rapidity and size of the two formations. The walls of the vessels are unusually brittle, and they are, therefore, liable to give way under the most trifling causes, producing those apoplectic depots which are so often seen in their interior, and those frightful hemorrhages which occasionally attend their open condition.

It is not unusual for encephaloid tumors to contain serous cysts, thus complicating their structure, and occasionally throwing a doubt over their diagnosis. In general, the cysts are small; but in one instance, within my observation, a cavity of this kind contained fully a pint of serum, its walls having a peculiar honey-combed appearance. Apoplectic depots are, as already stated, most common in the hematoid variety of encephaloid growths.

It is seldom that an encephaloid tumor, after having taken a fair start, remains even temporarily stationary; on the contrary, its tendency is to proceed, steadily and regularly, in its work of disorganization, until it destroys life either by hemorrhage, by irritation, or by visceral complications, the period at which this takes place varying, on an average, from nine to twelve months. Death sometimes occurs in an almost incredibly short period. Great softness of texture, bulk, and rapidity of growth are the circumstances which particularly predispose to an early unfavorable issue.

The period at which an encephaloid tumor becomes an open ulcer is indefinite; sometimes this takes place within a few months, at other times not under a year, or a year and a half from the first appearance of the disease, although this is uncommon. The immediate cause of the ulceration is the pressure of the morbid mass upon the skin, the formation of an abscess, or the occurrence of a slough, leaving a sore, the edges of which are thin, undermined, jagged, or irregular, while the bottom, which is sometimes of considerable depth, has a foul, bloody, fungous aspect. The parts immediately around are of a deep red, livid, or purple color. The discharge is usually profuse, and of a sanious, ichorous, bloody, or sanguinolent character, pure laudable pus being rarely, if ever, met with. Copious hemorrhage occasionally takes place, especially in the hematoid variety of the disease, and by its frequent repetition rapidly undermines the general health, urging on the fatal crisis. The occurrence is particularly common in encephaloid of the uterus and mamma. Of the many cases that I have seen of the encephaloid ulcer, not one ever healed even temporarily. Intractability is one of its distinguishing features.

Lymphatic involvement often occurs at an early stage of the disease, sometimes, indeed, long before ulceration sets in; at other times, however, not until the tumor has become an open sore. The general law is that the more rapid the growth is the earlier will there be disease in the neighboring lymphatic glands, and conversely. The constitutional cachexia is always well marked in the more advanced stages of the affection, and the patient's doom is often depicted in legible characters upon his countenance several months before it is finally sealed in death.
An encephaloid tumor is distinguished by its comparative softness, by the rapidity of its growth, by its great bulk, and by its lobulated surface. The pain is generally slight, at least until the occurrence of ulceration; and there is occasionally considerable, sometimes, indeed, enormous, enlargement of the subcutaneous veins with more or less involvment of the neighboring lymphatic glands. In its earlier stages, the tumor is movable, as in scirrhus, but as it advances it contracts adhesions, and at length becomes permanently fixed.

3. EPITHELIOMA.

There is a class of affections which was formerly known under the name of scirrhus, from its supposed identity with that disease, but which modern research has shown to be so different from it as to entitle it to be regarded as a separate formation. The affections comprised under this head are the various forms of malignant disease of the cutaneous and mucous tissues, more particularly carcinoma of the lip, gums, tongue, face, anus, rectum, uterus, vagina, and penis. They are not, however, limited to these parts; for they sometimes invade, secondarily, the deeper structures, as the bones, muscles, lymphatic glands, liver, and lungs, although their occurrence here is very uncommon. The name by which these formations are now generally designated is epithelioma, or epithelial carcinoma.

Epithelioma is more common in men than in women, the latter being more liable to scirrhus. Of 1467 persons admitted into the Cancer Hospital in London, on account of this disease, 1022, according to the statement of Dr. Marsden, were males. In men the lip and penis are most frequently attacked. What is called chimney-sweeper's cancer is merely a form of epithelial disease of the scrotum. Rodent ulcer, or the noli me tangere of the older writers, is nothing but epithelioma of the skin of the face and other parts of the body, an affection sufficiently common in both sexes, and often committing the most frightful ravages. Epithelioma occurs also in the tongue, at the anus, in the rectum, in the uterus, in old scars, and in chronic ulcers. The cauliflower excrescence of the uterus, first described by John Clark, of London, belongs to this variety of carcinoma. Whatever the form may be, the disease seldom shows itself before the age of thirty-five or forty, and then usually only in one part of the body.

The causes of this disease are generally inappreciable. Sometimes it is directly traceable to external injury, as a blow, long-continued pressure, or some particular irritation. Thus, Dr. Da Costa has mentioned to me the case of a shoemaker, where it was clearly attributable to the effects of a small board worn habitually upon the abdomen while the man was working at his trade. A man, aged fifty-nine, consulted me on account of a carcinoma of the lip and cheek, induced by a wound received five months previously from the prong of a fork in eating. Epithelioma of the lip is often charged to the irritation produced by the pipe in smoking. Chimney-sweeper's cancer is generally supposed to be occasioned by the lodgment of soot in the folds of the scrotum. Sometimes the disease originates in a wart, mole, or cicatrice. Epithelioma of the penis has been very commonly referred to the irritation arising from want of cleanliness due to the existence of a long and tight prepuce. A sharp tooth, constantly brought in contact with the tongue, may, it is believed, serve as an exciting cause of carcinoma of that organ. In 1866, I excised from the bridge of the nose of a lady, seventy-five years of age, an open epithelial tumor, fully half an inch in thickness and diameter, induced six weeks previously by the accidental prick of a needle. In 1877, a man, upwards of forty years of age, was brought to the College Clinic on account of a small epithelial growth on the right cheek caused by a slight wound inflicted with the razor in the act of shaving less than two months before.

The disease sometimes originates in the scar of an old burn, as in the case of a middle-aged man, a patient at the College Clinic, whose arm I amputated at the shoulder, in 1864, on account of an enormous epithelial ulcer consequent upon an injury of this kind received ten years previously. Many years ago I attended a young man for an epithelial ulcer of the anus, which had its rise, apparently, in a protracted eczematous affection of the skin and mucous membrane. Mr. Shaw, of London, has published the particulars of a case in which the disease suddenly broke out in an issue which had been kept open for thirty-five years; and Mr. Clark successively amputated both legs of a man whose bunions, long in a state of ulceration, had been invaded by epithelial carcinoma. Mr. P. C. Delagarde, of the Devon and Exeter Hospital, England, has reported two cases of epithelioma of the cicatrice of a burn, coming on, respectively, forty and sixty years after the accident.

Cases have been collected which tend to prove that the disease occasionally manifests a

hereditary predisposition. Dr. Foster, of Terre Coupee, Indiana, has communicated to me the particulars of three cases which occurred in three members of the same family, two having died of epithelioma of the face, and one of epithelioma of the foot.

The form which epithelial carcinoma assumes is greatly influenced by that of the structures in which it is situated. Its outlines are, as a general rule, so ill-defined and irregular as to defy accuracy of description. The most common varieties are the tuberculated, mammillated, and cauliflower-like. Now and then they present a lobulated, conical, disk-shaped, pedunculated, or even a pendulous appearance.

Epithelioma generally begins as a tubercle, crack, or wart-like excrescence, hard to the touch, movable, and somewhat tender on pressure. As the disease advances, it extends in different directions, and assumes a more distinctive character. By and by ulceration sets in, sometimes almost simultaneously at several points, the exposed surface having a foul, unhealthy, fungating appearance, with irregular granulated edges, and a hard, rough base. The discharge is generally abundant, and of a thin, sanious, acrid description, often eroding the skin in the neighborhood. The ulcer is intractable, manifesting no disposition to heal, or, if granulations form, they speedily degenerate and lose their vitality, their recuperative powers being too feeble to carry on the work of repair. Once begun, the disintegrating action never stops, and hence its ravages are often most frightful, as, for example, in the case from which the adjoining cut, fig. 63, was copied, where the disease successively involved skin, muscle, bone, cartilage, and fibrous membrane, sparing nothing that came in its way. The pain, like that of scirrhus, is of a sharp, darting, or pricking nature, and often extends through the surrounding parts. Hemorrhage occasionally occurs, chiefly in the fungating form of the epithelial ulcer, and may be sufficiently copious to cause serious debility, especially when an artery or a vein of considerable size is laid open.

During the progress of the disease, lymphatic involvement occurs; sometimes early, but generally not until after the eighth, twelfth, or fifteenth month. The constitutional suffering, also severe, usually sets in later than in ordinary carcinoma, although ultimately it is not less fatal.

Fig. 63.

Epithelial Carcinoma in a state of Ulceration.

Occasionally the disease shows itself successively in a great number of organs. In a case observed by Virchow, in a man, seventy-three years of age, it affected both lips, lymphatic glands, clavicle, ribs, lungs, heart, liver, and kidneys. In the cylindrical-celled variety of the disease secondary growths in the lymphatic glands are not uncommon, and the viscera are occasionally affected.

Epithelioma consists essentially of an ingrowth of epithelial cells into the deeper tissues. Its stroma is not like that of the alveolar connective-tissue matrix of scirrhus or encephaloid, although it is analogous to it, and the cells retain the type of those of the surface from which the growth originates. When the skin is affected the cells resemble epidermis cells; when the tubular glands of the intestine are the source of origin of the tumor, the cells, on the other hand, are cylindrical. Hence, epithelioma is anatomically divided into the pavement-celled, and the cylindrical-celled varieties. In the former variety, which is so common about the face, penis, labia, and uterus, the squamous epithelial cells are arranged in simple or branched cylinders or plugs, which grow into the stroma of the cutis or connective-tissue framework of the mucous membrane. These appearances are well represented in fig. 64, from Green. As the cells grow older they are very frequently closely packed together, forming nests, and assuming a concentric arrangement, like the layers of an onion. They are often visible to the naked eye, and are very characteristic of, although not entirely peculiar to, epithelioma. In the cylindrical-celled tumor, which is found in connection with mucous membranes with columnar epithelium, as those of the stomach, rectum, and uterus, the cells are arranged on the walls of the connective-tissue stroma after the normal type. These growths have a soft consistence, readily ulcerate, and are disposed to bleed.

Epithelioma is generally comparatively tardy in its growth. In a case of epithelioma of the tongue, reported by Dr. Da Costa, twenty-two years elapsed from the appearance of the disease to the time of its removal by operation. In the lip the disease often lasts a number of years before it terminates fatally, although this is not its ordinary tendency, for most

persons die in from eighteen months to two years. I have seen rodent ulcer of the face continue its ravages for nine, fifteen, and even twenty-five years before it finally caused

Fig. 65.

Minute Structure of Cylindrical-celled Epithelioma.

death. Under such circumstances, the ulceration occasionally ceases for a time, and then recurs, perhaps now with increased vigor.

No experiments that have yet been performed to test the inoculability of epithelioma have been successful. A clinical observation, however, published by Mr. Nunn, of London, seems to countenance such a view. A woman, thirty-four years of age, had a carcinoma of the rectum, which perforated the posterior wall of the vagina, forming a fistulous opening the size of a goose-quill. On the anterior wall of the vagina, exactly opposite this opening, and in immediate contact with it, was a small, inflamed circular patch, superficially ulcerated, studded with little red granulations, presenting, under the microscope, all the characteristic features of carcinoma. Here the mere contact of a healthy with a diseased surface was, apparently, sufficient to propagate the growth.

4. COLLOID.

Colloid is one of the most uncommon of the carcinomatous formations. The name by which it is now usually known has reference to the peculiar jelly-like appearance of one

of its principal constituents, and is therefore quite appropriate. It has also been described under the terms gelatiniform, alveolar, cystic, and gum cancer.

The favorite seats of this morbid product are the liver, stomach, rectum, ovary, and mamma.

Although colloid may appear, simultaneously or successively, in a considerable number of organs, it manifests less tendency to general diffusion than any of the other carcinomatous formations, except the epithelial. It is rarely met with before the fortieth year, and is most common between forty-five and fifty-five years.

Colloid appears under two varieties of form, as a tumor and as an infiltration, the latter being most common in the alimentary canal, particularly the stomach and rectum; the former, in the mammary gland and ovary. In the infiltrated variety, the new matter occupies the meshes of the connective tissue, forming cysts, from the size of a mustard seed to that of a hazel-nut, which are filled with the characteristic jelly-like matter, and which, as they increase in volume and number, so completely subvert the primitive structures as ultimately to leave no trace of them. In the other variety of colloid, there is a distinct tumor, from the volume of a marble to that of an adult head, of a globular, rounded, or irregular shape, and of a firm, dense consistence.

The surface of the colloid tumor is generally rough, knobby, or distinctly lobulated, according to the volume and arrangement of the component cysts. Occasionally it bears a strong resemblance to the exterior of a pudding stone. In the larger masses, vessels of considerable size may be seen running over the surface, and penetrating the walls of the principal cysts, without, however, passing through their contents.

Colloid consists of two component elements, a stroma, and the peculiar cell-containing, jelly-like matter from which the neoplasm derives its distinctive features. The former is of a fibrous character, and is arranged in such a manner as to form cells, loculi, or cavities, from the size of a pin-head up to that of a small marble, rounded, ovoidal, or angular, and communicating with each other. The stroma generally possesses great firmness and density; it creaks under the knife, and is of a dull, whitish, grayish, or pale yellowish color. It receives an abundant supply of vessels, as I have satisfied myself by dissection, and as is evinced also by the rapid development of the morbid growth, and the great bulk which it occasionally attains. In one case, in particular, I had no difficulty in tracing several large, straggling arteries into

Fig. 66.   Fig. 67.

Colloid Carcinoma. Fig. 66 exhibits the External Appearance, and Fig. 67 the Internal Structure.

a tumor of this kind, showing that it had a very active circulation. The cystiform structure of colloid is easily recognized, as it constitutes one of the most remarkable features of the morbid growth. It is well illustrated in the annexed cuts from a preparation in my collection; fig. 66 showing the external arrangement, and fig. 67 the internal.

The other element of colloid is an unrecognizable product, of a whitish, greenish, or yellowish color, and of the consistence of ordinary jelly, whence the name by which the disease is usually known. In the older spaces the matter is sometimes as firm as moist cheese, or the albumen of a hard-boiled egg, opaque, and of a white, pearly, or yellowish hue, interspersed with minute dark points. Sometimes, again, it resembles currant jelly, half-dissolved glue, or a solution of gum shellac. However this may be, it never adheres to the walls of the alveoli, and is, therefore, easily enucleated, or pressed out. When perfect clearance has been effected of the loculi of a mass of colloid, the fibrous structure exhibits very much the appearance of a piece of sponge, the alveolar arrangement being then particularly conspicuous, hundreds of cavities being often visible upon a surface less than an inch in diameter.

Under the microscope colloid differs from scirrhus and encephaloid mainly in the large size of the alveoli and in the contained gelatinous material, within which are included the so-called colloid corpuscles, or large, refractory, vacuolated cells, which are sometimes marked by several delicate concentric lines, giving them an oyster-shell appearance. With the advance of the metamorphosis, the cells disappear almost entirely, and nothing remains except large laminated spaces, from the $\frac{1}{60}$ to the $\frac{1}{100}$ of an inch in diameter, usually oval and grouped, nearly transparent, and interspersed with elongated nuclei, small, nucleated cells, and brood cells. The annexed sketch, fig. 68, from Rindfleisch, magnified 300 diameters, shows the alveolar formation of the stroma, and concentric cir-
Fig. 68.

Minute Structure of Colloid.

cles interspersed with granular matter and slender nuclei, and inclosing oval, well-defined, nucleated cells. This arrangement is very common, and most characteristic of colloid carcinoma.

From the fact that colloid was until a comparatively recent date confounded with myxoma, it is impossible, in the existing state of our knowledge, to assign to it a proper position in the scale of the carcinomatous formations. In the mammary gland, in which organ he has carefully studied its clinical features, Dr. S. W. Gross finds that, when compared with scirrhus, its progress is slow, that the lymphatic glands are affected late in the disease and in only one-fourth of all cases, and that metastatic tumors form only after it has existed for several years. The comparative immunity of colloid from local and general dissemination is ascribed by Dr. Gross to the fact that the migration of the cells along the lymphatics to the associated glands and the viscera is delayed or prevented by the colloid degeneration, a change which acts the part of a cementing substance and renders the cells immobile.

5. MELANOSIS.

Melanotic or pigmented carcinoma is a variety of encephaloid carcinoma, the only difference being that the cells of the former are impregnated with melanin, the appearances of which are represented in fig. 69, from Bennett. It has been observed in the breast, ovary, rectum, and parotid gland, but the history of its life is so mixed up with that of melanotic sarcoma that scarcely anything is known of its clinical features.

Fig. 69.
Pigmented Cells of Melanosis.

After having remained stationary for an indefinite period, the tumor manifests a disposition to disintegration, the softening process generally beginning at some superficial point, and thence gradually leading to the establishment of a foul, non-granulating, unhealthy ulcer, which no skill can cure. The discharge is generally of a sanious character, mixed with and discolored by the pigment. Its progress is usually more tardy than that of scirrhus; but the general health often suffers long before ulceration sets in, the patient becoming thin, haggard, sallow, and exhausted.

DIAGNOSIS OF CARCINOMATOUS TUMORS.

Epithelioma is usually sufficiently easy of recognition. Its situation at the junction of the skin and mucous membranes, or upon either of these structures; its origin in a crack, fissure, or wart-like excrescence; its extraordinary firmness, the part feeling like a mass of fibro-cartilage; its slow growth; its small size; and the absence, for a long time, of severe pain and constitutional taint, are features that cannot deceive.

The only characteristic sign of melanosis is the peculiarity of the color of the tumor; hence, when it is situated superficially, as when it occupies the parotid region, it is quite impossible to mistake the nature of the disease.

Colloid tumors are liable to be confounded with fibrous, cartilaginous, myxomatous, and sarcomatous formations; but a careful consideration of the history of the case, and a thorough examination of the morbid growth, will generally serve to clear up any doubt that may arise in regard to the diagnosis. Colloid tumors are tardy in their progress, smooth or rough on the surface, of uniform consistence, and free from pain, their bulk being usually small, and the general health greatly disordered. Fibrous tumors enlarge slowly, seldom attain a great bulk, and do not usually seriously undermine the constitution. The cartilaginous growth is harder and less elastic than the colloid; its progress is rather

rapid, and its outlines are always well defined, which is seldom the case with alveolar carcinoma. A sarcoma often attains an immense size in a few months, especially in the bones, jaw, and the mammary gland, is generally of a globular shape and uniform consistence, and seldom contaminates the neighboring lymphatic glands. Myxoma is softer, grows more rapidly, and attains a far greater volume than colloid; the former is not characterized by adhesions or lymphatic involvement; and metastatic tumors are infinitely less common than in colloid.

Almost the only diseases with which encephaloid is liable to be confounded are scirrhus and sarcoma, and it will be therefore necessary to point out their differential diagnosis. For this purpose I give the subjoined table of the characteristics of the three affections.

ENCEPHALOID.	SCIRRHUS.	SARCOMA.
1. The tumor is soft and elastic, but not uniformly.	1. Uniformly hard and inelastic, feeling like a marble beneath the skin.	1. May be firm, tense, and elastic; generally uniformly soft, and apparently fluctuating.
2. It grows rapidly and soon acquires a large bulk, perhaps ultimately attaining the volume of an adult's head.	2. Growth is slow, and bulk comparatively small; the tumor rarely, even in the worst cases, exceeding the volume of a large fist.	2. May remain stationary, or nearly so, for many years; awakened into activity, it progresses more rapidly than encephaloid, and may attain an enormous volume in a short time.
3. The pain is slight, and erratic, until ulceration begins, when it becomes more severe and fixed.	3. The pain begins early, is distinctly localized, and is of a sharp, darting, burning, or lancinating character.	3. Rarely pain until ulceration sets in, and even then usually insignificant.
4. There is nearly always marked enlargement of the subcutaneous veins.	4. In scirrhus these vessels retain their natural size, or are only slightly enlarged.	4. The subcutaneous veins only slightly, if at all, enlarged.
5. The ulcer is foul, deep, and excavated, with thin, undermined, and livid edges, and is subject to frequent and copious hemorrhage.	5. The ulcer is incrusted with spoiled lymph, and has steep, abrupt edges, looking as if it had been scooped out of the part; bleeding little, and seldom.	5. The ulcer is fungous, and subject to frequent and copious hemorrhage.
6. There is generally early lymphatic involvement.	6. Usually not until late, or shortly before ulceration occurs.	6. Singularly free from lymphatic involvement, or, if the glands are affected at all, they become so quite late.
7. More frequent before the age of forty-five than scirrhus.	7. Seldom before the age of forty-five.	7. Generally before the age of forty, and most commonly between that age and twenty.
8. Is most frequent in the mamma, testicle, ovary, prostate, and salivary glands.	8. Rarely occurs in the testicle, ovary, and prostate.	8. Always begins in the connective tissues, particularly sarcoma of the extremities; most common in periosteum, bones, and the mamma.
9. The disease usually terminates fatally in from nine to twelve months.	9. Seldom sooner than eighteen months or two years.	9. No reliable data; patients, however, often survive many years, even after repeated extirpation.

It is not improbable that an encephaloid carcinoma might be confounded with a chronic abscess, or an aneurism, especially when it is so situated as to receive an impulse from a neighboring artery. The very mention of the possibility of such an occurrence will be sufficient to put the practitioner upon his guard, and serve to point out to him the absolute necessity of the most profound caution in every case of a suspicious character.

SECT. VII.—TREATMENT OF MORBID GROWTHS.

In their management, tumors may, for the sake of convenience of description, be divided into the benign and malignant. The former comprise the cystic, fatty, fibrous, cartilaginous, osseous, muscular, vascular, lymphangiomatous, neuromatous, adenomatous, and papillary formations. The latter include myxoma, sarcoma, lymphoma, and carcinoma.

1. TREATMENT OF BENIGN TUMORS.—The treatment, medical as well as surgical, of innocent tumors, having been succinctly discussed under each respective variety, it is only necessary here, in order to place the whole subject in a more tangible form, that I should briefly recapitulate the more prominent points of what has already been said.

Few, if any, of the innocent formations are in the slightest degree amenable to remedies, whether locally applied or internally administered. The more simple forms of cystic tumors, and certain forms of goitre, occasionally disappear under topical and constitutional treatment; but even in these, in many cases, we find ourselves completely baffled, however perseveringly or judiciously the curative plan may be carried out. The most trustworthy local remedies, unquestionably, are tincture of iodine and the ointment of biniodide of mercury, variously diluted, and applied once or twice in moderation in the twenty-four hours. Chloride of ammonium also possesses powerful solvent properties. A poultice made of bran and salt water is an excellent sorbefacient. Leeches and blisters are useful when the morbid growth is hot and congested, or actually inflamed; and, under similar circumstances, great benefit occasionally accrues from lotions of acetate of lead and Goulard's extract. Systematic compression with adhesive strips, the roller, or the air-cushion, is sometimes serviceable, as is shown in certain tumors of the mammary gland, the testicle, and other parts of the body.

The only internal remedies at all worthy of consideration, in the treatment of benign tumors, are iodine, either in substance, tincture, or Lugol's solution, iodide of iron, iodide of potassium, mercury, chloride of ammonium, and tartar emetic. These articles may be given by themselves, or in various forms of combination, care being taken that the dose is not so large as to oppress the stomach, and that the prescription be occasionally pretermitted for a short time, as the effects are thus greatly enhanced. The diet must, of course, be properly regulated, being light, non-stimulant, and at the same time not too nutritious; the bowels are kept gently open, and the utmost attention is paid to the maintenance of the secretions.

How far electrolysis is to be trusted in the treatment of innocent tumors is a problem which further experience alone can solve. The chief affections in which it has been employed are, hydrocele, hydatid tumors of the liver, nævoid growths, and certain forms of goitre, in which it has occasionally been beneficial, having been followed, in some of the cases, by a permanent and rapid cure. The manner in which electrolysis acts is probably by the induction of inflammation, the perturbating effects of which put a stop to further growth at the same time that they promote the absorption of its various constituents, fluid as well as solid. To the harder varieties of innocent tumors, as the fibrous, cartilaginous, and osseous, this method of treatment does not seem to be adapted: at all events, I am not aware that any successful cases of it have been reported. A similar remark is applicable to the various forms of ordinary cysts and lipomas. Papillary growths, as warts on the skin and genital organs, have occasionally been cured by it.

With respect to the removal of innocent tumors, a few precepts may here be introduced for the guidance of the surgeon. The knife, of course, always claims preference in every operation of this kind; but now and then a case occurs in which, on account of the danger of hemorrhage, or the difficulty of access, the écraseur is used. The practice of removing innocent tumors with caustics has long been obsolete.

1st. Interference should, as a rule, be avoided when the tumor is stationary, or nearly so, painless, and not inconvenient by its size, weight, or situation.

2dly. If an operation be determined upon, the system should always be subjected to a certain degree of preliminary treatment, even when the tumor is comparatively small, experience having shown that extirpation is often followed by erysipelas.

3dly. While the object should be to effect the most thorough removal, care should be taken not to interfere unnecessarily with the surrounding tissues, but to respect them as much as possible by keeping the knife in close contact with the morbid growth.

4thly. When the tumor is of unusual bulk, it will generally be necessary to remove a portion of skin by including it in an elliptical incision, otherwise it should be retained, due allowance being made for its astonishing contractile powers. If this precaution be neglected, there may be a deficiency of flap when the surgeon comes to approximate the edges of the wound.

5thly. Diseased integument should always be removed along with the morbid growth, the knife being carried around it elliptically.

6thly. Extirpation may generally be readily effected by a single incision carried across the centre of the tumor, either vertically, horizontally, or curvilinearly. It is only when, as already stated, the morbid growth is very large, or when there is diseased integument, that an elliptical incision will be required.

7thly. The incisions should be directed in such a manner as to favor drainage, and to prevent bagging. Hence, one of the extremities should always correspond with the most dependent portion of the tumor. In operating upon parts that are habitually exposed, as

the face, head, neck, hand, and arm, it is a matter of great importance to avoid the occurrence of unseemly scars. To facilitate this object, the skin should, as originally suggested by Dr. John H. Packard, be divided obliquely, the knife being held edgewise in making the incisions, so as to impart to the borders of the wound a bevelled appearance. A wound thus made, heals, Dr. Packard thinks, more readily than one made with a straight cut, and hardly leaves a perceptible cicatrix.

8thly. When the morbid growth is very vascular, uncommonly soft, or very firmly adherent to the integument, the removal will be greatly facilitated if the skin be divided, as a preliminary step, upon the grooved director, the knife being thus prevented from penetrating the proper substance of the tumor.

9thly. By keeping the knife in close contact with the tumor, the whole mass may sometimes be speedily and effectually enucleated with the hand, finger, scalpel, scissors, or scraper. Another advantage of such a precaution is the avoidance of hemorrhage.

10thly. When the mass is very large, pendulous, and vascular, as, for example, in those enormous growths constituting what is called elephantiasis of the scrotum, the bleeding may be essentially diminished by elevating the tumor and pressing the blood out of its veins immediately prior to the operation either with the hands or with the elastic bandage.

11thly. There are certain kinds of morbid growths, as, for example, polypoid myomas of the uterus and nævoid tumors, that are more easily and safely removed with the écraseur than with the knife, on account of their peculiar situation, and the danger of hemorrhage. In using this instrument, the part, as a preliminary step, is thoroughly isolated by transfixing its base with pins, and then gradually divided by linear crushing, the chain with which it is provided being well adapted to such an object. The stump must not be disturbed after the operation is completed, as this might excite bleeding and interfere with the healing process.

12thly. Any large arteries that may be divided should either be compressed by an assistant until the extirpation is completed, or they should immediately be tied, loss of blood being carefully guarded against in all proceedings of this kind. When the surgeon is operating alone, or when he has no good aids, the bleeding may be temporarily checked with the serrefine, fig. 70, a kind of wire forceps, the contrivance depicted in fig. 71, or Nunneley's forceps, fig. 72. These instruments maintain their hold by their own elasticity, and will be found to be of great service in extensive and tedious dissections, especially when the same artery is obliged to be cut several times.

Fig. 70.   Fig. 71.   Fig. 72.

Serrefine.   Small Forceps for Temporarily Checking Hemorrhage.   Nunneley's Artery Forceps.

13thly. When all oozing of blood has ceased, the edges of the wound are accurately approximated by suture and adhesive strips, aided, if necessary, by a light compress and bandage, to keep the flaps in close contact with the raw surface beneath, as the object is to secure union by the first intention.

Lastly. The part is to be kept perfectly at rest until the wound is healed, and the case treated, in every respect, upon ordinary antiphlogistic principles, the greatest attention being paid to drainage and cleanliness. In general, the dressings should not be disturbed before the end of the second day, especially if the absence of fetor and discharge indicates favorable progress.

2. TREATMENT OF MALIGNANT TUMORS.—In the treatment of the various forms of malignant growths all internal remedies, of whatever kind and character, have proved unavailing in arresting their march, or in modifying their action so as to render the surrounding structures tolerant of their presence. The vaunted specific of the empiric, and the enchanted draught of the honest but misguided enthusiast, have alike failed in performing a solitary cure; and the science of the nineteenth century must confess, with shame and confusion, its utter inability to offer even any rational suggestions for the relief of this class of affections. But, although this is the case, yet it by no means follows that the subjects of these complaints may not be benefited by general treatment, if it be directed by common sense and sound judgment. Every practitioner of experience knows how

much ordinary local diseases are influenced by constitutional measures; and if this be true of these lesions, how much more true must it be of the malignant, in the production of which both the solids and fluids play such an important part. Hence, when surgical interference is inappropriate, the attention of the surgeon should be particularly directed to the patient's diet, bowels, and secretions, and to the avoidance of all sources of local irritation, calculated to favor the morbid growth, and hasten the fatal issue.

The diet should generally be of a bland and unirritant character, and yet at the same time sufficiently nutritious to preserve a sound condition of the blood, and to maintain the tone of the muscular system. All condiments, coffee, strong tea, pastry, hot bread, and the coarser kinds of vegetables and meats, should be abstained from. Eggs, fish, oysters, and the white kinds of meat, may be moderately used once a day, but not oftener, unless there is some special reason for it, founded upon the state of the general health. Frequently a purely farinaceous and milk diet will be found to answer better than any other, the patient not only thriving under it, but the disease being apparently kept in check by it.

The bowels should be maintained in a soluble condition, but all active purgation must be carefully avoided. The most suitable aperient, when a tendency to constipation exists, is a blue pill, with one grain of ipecacuanha, or equal parts of blue mass and jalap, at bedtime, followed, if necessary, by a Seidlitz powder in the morning. If gastro-intestinal irritation arise, the blue mass may advantageously be replaced by a small portion of calomel. In this way, while the bowels are maintained in an open state, the secretions are also duly preserved; a matter of no little moment in the treatment of all malignant diseases without exception, especially when they are attended with marked constitutional disturbance.

Sleep is procured and pain allayed by morphia given, if possible, hypodermically once or twice in the twenty-four hours. When the suffering is of a neuralgic character, the anodyne may be administered by the mouth in union with arsenic or arsenic and strychnia.

When marked debility exists, tonics, as quinine and iron, a generous diet, and the use of brandy, wine, ale, or porter, are imperatively demanded. Night sweats are best controlled by sulphate of atropia, aromatic sulphuric acid, oxide of zinc, or acetate of lead and tannic acid.

Perfect rest of the affected part, and entire freedom from pressure and excitement, are of paramount moment. Thus, in carcinoma or sarcoma of the breast or testicle, the organ must be well suspended, the dress worn loose, and all rude manipulation scrupulously abstained from. If the part be tender, hot, and swollen, or œdematous, some mildly astringent and anodyne lotion will be of service, or the surface may be painted several times a day with a weak solution of iodine. When the local inflammation is unusually severe, as evinced by the discoloration and pain, nothing, according to my observation, affords such prompt and decided relief as the application of a few leeches, unless it be a small blister, retained until free vesication is produced. Some cases are greatly benefited by the use of an opium, belladonna, or cicuta plaster, renewed every eight, ten, or twelve days. All caustic applications should be carefully avoided, inasmuch as they can never do any good, but may do a great deal of harm by establishing sores which it will afterwards be impossible to heal.

In open malignant growths, the sore must be kept constantly clean by frequent ablutions; while the excessive fetor which so generally attends must be allayed by the free use of permanganate of potassium and other articles. The best dressing is an emollient poultice, particularly one made of powdered elm bark, sprinkled, if there is much pain, with a little morphia, pulverized opium, or laudanum. If the ulcer is very sensitive, it should occasionally be very lightly touched with solid nitrate of silver, or kept constantly covered with very dilute ointment of acid nitrate of mercury. When the discharge is very profuse, sanious, and offensive, a lotion composed of two to four drops of nitric acid to the ounce of mucilage of gum arabic, or of five grains of chloral to the ounce of water or cosmoline, will be found exceedingly beneficial in diminishing its quantity and changing its character. Carbolic acid is also an excellent remedy, the only objection to it being its offensive odor.

The affected glands in the neighborhood of the diseased organs often require attention, especially when they are very painful and bulky. The remedies should be of an anodyne and antiphlogistic character, especially leeches, iodine, and saturnine lotions in union with laudanum.

The hemorrhage attendant upon open carcinoma is generally easily controlled with Monsel's salt, or a thick coating of Richardson's styptic, consisting of collodion with the addition of three grains of tannic acid to each ounce of fluid. Acupressure may be required when a small artery or vein has been laid open.

The electrolytic treatment of malignant growths has, on the whole, been very unsatisfactory. The details of the reported cases are obscure, and the tumors said to have been malignant, and removed by this measure, have rarely exceeded the volume of a nutmeg, so that errors in diagnosis were not out of the question. In the majority of instances the sole results appear to have been amelioration of the suffering, and, in a very few, temporary arrest of growth.

The treatment of carcinomatous diseases by compression, introduced early in the present century by Sir Charles Bell, has, after having been alternately eulogized and condemned, at length fallen into merited disrepute. Many years ago, Mr. Arnott, of London, made an attempt to revive this mode of treatment, especially in carcinoma of the mammary gland, by the invention of a cup-shaped apparatus furnished with an elastic air-cushion, in order to apply the pressure in a more gentle and equable manner. The suggestion, emanating from so eminent an authority, attracted much attention at the time, and led to numerous trials, both in Europe and in this country, but with results so discouraging as to have caused its entire abandonment.

In 1866, Dr. Broadbent, of London, called attention to the treatment of carcinoma by means of the hypodermic injection of acetic acid diluted with two to five parts of water, the quantity introduced at each operation varying from twenty to thirty minims. Cases are cited in which its use is said to have been followed by marked diminution of the volume of the tumor, but as no examples of permanent cure have been reported the practice has been abandoned. I have myself, in the few trials I have made with it, obtained no benefit. In several of the cases the operation was followed by a smart attack of erysipelas and by a good deal of ulceration. The treatment of lymphoma by parenchymatous injections of Fowler's solution is not only attended with depression, restlessness, sleeplessness, and fever, but its employment holds forth no prospect of ultimate recovery.

In regard to extirpation, if it be done early and in a thorough manner, so as to remove all diseased tissues, recent experience has demonstrated that it may be relied upon in a certain proportion of cases as a means of permanent cure. In other cases, the results are not so striking; but there are hundreds of examples of carcinoma, sarcoma, lymphoma, and myxoma on record, which prove conclusively that life may be extended many months and even years by timely interference, and by the removal of recurrent growths as fast as they make their appearance. Hence my conviction is that the knife should be resorted to as early as possible, and that no time should be wasted in the employment of the measures indicated in the preceding paragraphs.

When a sarcoma, or myxoma, is seated in one of the long bones, or deeply among the muscles of an extremity, the only resource is amputation of the limb, performed at the nearest articulation. To remove a limb in its continuity, in such a condition, is worse than useless, conferring neither benefit upon the sufferer, nor reflecting any credit upon the judgment of the surgeon.

Epithelioma is less liable to recur after extirpation than scirrhus, encephaloid, or melanosis. Removed in its earlier stages, there is occasionally a strong probability that there will be either no relapse at all, or only after a considerable period. One reason perhaps of this is that the disease is commonly more localized than the ordinary forms of carcinoma.

General Rules for conducting Excision of Malignant Tumors.—When excision is determined upon, it is very essential that it should be performed in the most thorough and complete manner, in order that the parts may be effectually protected from relapse. The slightest atom of the new tissue, the most minute cell, nay, possibly, the smallest particle of juice, may, if left behind, endanger reproduction.

1st. To accomplish this object, it is necessary that the incisions should be carried through the healthy tissues some distance beyond the morbid growth. If any part has escaped the knife in the first instance, it should be traced out immediately after the extirpation of the main mass, and be excised with the most scrupulous exactness. Free use should be made, in this stage of the operation, of the sponge and finger; of the former for clearing away the blood, of the latter for ascertaining the consistence of the surface of the wound. The sight alone should never be trusted, inasmuch as it is a great deal more deceptive than the sense of touch. Not a particle of the least suspicious substance should be left behind. Nay, the very atmosphere of the disease should be destroyed. Skin, muscle, glands, vessels, nerves, and bone should all be sacrificed, if necessary to success.

2dly. When only a portion of an organ is involved by a malignant growth, the rule is to remove, not a part, but the whole of it. Thus, in carcinoma or sarcoma of the mammary gland, the practice invariably is to extirpate the entire organ, however small the part implicated.

3dly. It is equally important to remove the associated contaminated lymphatic glands, and even search for them if they were not palpable previous to the operation. In carcinoma of the breasts of fat women, laying open the axilla will frequently bring to light infected glands which could not be felt from the surface. If permitted to remain the object of the operation will be defeated.

4thly. The utmost care must be taken to guard against hemorrhage, even when the patient is tolerably plethoric, especially if the operation is at all severe. Lean and fat subjects generally bear the loss of blood badly. A copious hemorrhage, besides seriously endangering adhesive action, is often followed by erysipelas, and I am fully satisfied that it predisposes to early relapse.

5thly. As a preventive against local reproduction the wound left by the operation should be mopped with a strong solution of chloride of zinc, or even seared with the cautery at a red heat. The latter agent is always indicated after the extirpation of secondary nodules in the adjacent muscles.

6thly. The edges of the large wound should be as closely approximated as possible by a few sutures inserted at least an inch from the edges and by adhesive strips. The most suitable dressings are an oiled compress and a bandage. When the parts are slow in healing, skin grafting may be employed.

7thly. When the skin is defective, it is sometimes practicable to borrow the requisite amount from the surrounding structures; an operation first suggested, I believe, by Martinet, who imagined that a return of the disease could thereby generally, if not always, be effectually prevented. He thought the functions of the parts might thus be changed in such a manner as to restore their healthy nutrition, and so counteract the tendency to the reproduction of carcinoma.

I have had recourse to this procedure in a number of instances, in different regions of the body, especially in epithelioma of the lips and eyelids; but in very few with any permanent or even protracted benefit. For a time the transplanted parts retained their healthy character; but at the end of a few months they gradually became hard and rigid, and soon thereafter exhibited all the evidences of carcinomatous disease.

8thly. When the morbid growth is seated in an extremity, and is of large bulk, or involves important structures, amputation takes the place of excision. Whenever the operation is performed for sarcoma of the long bones, experience has shown that there will be no return of the disease in the stump, provided care has been taken to remove the limb above the limits of the tumor. Death, however, commonly occurs, except when the sarcoma is of the myeloid variety, at no distant date from a development of similar disease in some of the internal organs, especially the lungs.

Finally, it is well to bear in mind that the surgeon, in the removal of a malignant tumor, may incur great personal risk as it respects his own health and life. Professor Dudley suffered for many months from the inoculation of his hand in amputating the forearm of a person affected with encephaloid sarcoma; and, in 1869, Dr. Maurice H. Collis, of Dublin, lost his life from the effects of a slight puncture of one of his fingers, received during the excision of a carcinomatous tumor of the upper jaw. Other examples of a similar nature are upon record. The symptoms are usually those of blood poisoning. Thorough ablutions, first with simple water and soap, and then with water impregnated with chlorinated sodium, are the best preventives.

Treatment after Operation.—The treatment after removal of the affected structures must be conducted upon general principles. When the patient has recovered from the immediate effects of the operation, he should be put upon a general course of treatment intended to maintain his health as near as possible at the normal standard. Above all, strict and constant attention should be bestowed upon his diet.

Of the propriety and importance of attention to the patient's diet, after excision, no one can entertain any doubt. The force of this remark will appear the more evident when it is recollected that the progress of carcinoma has occasionally been stayed for months, and even years, by a regular and persistent system of starvation, barely allowing a sufficient quantity of food, of the most bland and unirritant character, to maintain the due play of the vital functions, without too great a reduction of the heart's action.

The kind of diet is a matter of no little moment. Meats, soups, and the coarser varieties of vegetables should generally be proscribed, on account of their heating and indigestible character. For the same reason, condiments, wines, spirits, coffee, and fermented liquors are to be eschewed. Among the more suitable articles are stale bread, toast, and soda biscuit, hominy, grits, rice, sweet and Irish potatoes, mush, macaroni, baked apples, figs, and ripe fruits. Oysters and fresh fish may be used in moderation. Not only

should the food be perfectly simple, and easy of digestion, but it should be well masticated, and taken in such quantity at each meal as not to crowd and oppress the stomach.   As drinks, the best articles are water, milk, and weak tea.

Of late years an almost exclusive milk diet has been used in several remarkable cases after this operation, with effects so encouraging as to deserve further trial.   The facts published upon this subject by Dr. Pierce, Dr. Bowditch, and others, are exceedingly interesting and instructive, and worthy of attentive consideration.

As there are no remedies which will eradicate the malignant structure from the system before the operation, so are there none which will prevent its reproduction after. Of the numerous articles that have been employed for this purpose there is not one which can be viewed in the light of a specific, or as a counter agent to the morbid action.

Some of the older surgeons, and, indeed, quite a number also of the modern, strongly insist upon the establishment of a kind of perpetual drain in the neighborhood of the original disease, as a means of preventing relapse after extirpation.   The principal measures that have been suggested for this purpose are the issue and seton ; modes of treatment with which I have no experience, and in which, on principle, I should have no confidence.

If relapse ensues, and the patient becomes debilitated, supporting measures must be adopted, as quinine, iron, brandy, and nutritious food, along with gentle exercise in the open air.   Pain must be allayed by the free use of anodynes, and night sweats by sulphate of atropia, elixir of vitriol, or oxide of zinc, given in as large doses as the stomach will tolerate.   Constant attention must be paid to cleanliness ; fetor must be corrected by chlorinated sodium, permanganate of potassium, and other means ; and the utmost care must be taken to protect the parts from the pressure of the clothes and from all kinds of rude contact.   The most suitable local remedies are leeches, dilute tincture of iodine, opiate plasters, and emollient cataplasms, medicated with anodynes.

Contraindications to Surgical Interference.—The following circumstances may be enumerated as contraindicating the removal of malignant tumors :—

1st. Interference should be avoided when the disease coexists in several parts of the body, as, for instance, in the mamma and uterus, or the testicle and eye, as it would be almost certain to hasten the patient's destruction.

2dly. No operation is ever resorted to, at least not as a curative agent, when there is serious local involvement ; or when there is marked evidence of the carcinomatous cachexia. Thus, in carcinoma of the mamma, no surgeon who values his reputation, or who has any regard for the welfare of his patient, interferes when the tumor is firmly adherent to the surrounding parts, when the skin is changed in structure, ulcerated, indurated, or dimpled, when there is enlargement of the axillary, subclavicular, or supraclavicular lymphatic glands, when there is œdema, with numbness and loss of function in the corresponding limb, and, finally, when, in addition to these symptoms, the countenance exhibits all the evidences of the carcinomatous cachexia.   The same circumstances guide the surgeon in carcinoma of the testicle, lip, penis, and extremities.   If the knife is ever employed when the malady has made such progress and such inroads, it is with a view solely to palliation, not to cure.   Of the propriety of such a course every surgeon must be his own judge.

3dly. When the disease advances very rapidly, as it not unfrequently does in encephaloid sarcoma, carcinoma, and myxoma, breaking through its original barriers, and leaping, as it were, suddenly into the surrounding tissues, ablation will either be improper, or, if had recourse to, speedy repullulation may be expected.   Rapid growth, constituting what has sometimes been denominated the acute form of malignant action, always implies a bad state of the constitution and extensive infiltration of the surrounding tissues, and imperatively forbids surgical interference.   An œdematous appearance of the parts immediately around the morbid deposit, or at a distance more or less remote from it, is another unfavorable occurrence.   This condition, which is seldom absent in external carcinoma in its later stages, is not unfrequently present at an early period in encephaloid, especially in the hematoid variety, and is always indicative of the very worst state of things, both local and constitutional.   The immediate cause of this symptom is obstruction of the lymphatic vessels and glands.   Observation shows that nothing but mischief is to be expected from interference when the malady has attained this crisis.

4thly. A quickened state of the pulse, occasioned by the local irritation, augurs unfavorably.   Excision, performed under such circumstances, is nearly always speedily followed by relapse.

5thly. Latent carcinomas should not be tampered with.   Cases constantly occur in which, from neglect of this precaution, the patient loses his life, within a very short period

after operation, from a return of the disease in its worst form. The reproductive powers of the part, if not of the system generally, usually manifest an astonishing activity under such circumstances, and the consequence is that the malady soon accomplishes its work of destruction.

6thly. It is not necessary to insist upon the propriety of refraining from operation when there is serious disease of an important internal organ. Such a complication could hardly fail to predispose to relapse, if not to the speedy destruction of the patient.

7thly. I was formerly greatly opposed, in malignant affections, to operative interference merely as a palliative measure, believing that the pain and risk consequent upon its employment, would not counterbalance the beneficial effects. After more mature experience, however, I came to a different conclusion, and for years past I have, in numerous instances, used the knife where there was not the slightest prospect of a permanent cure. The class of cases to which this procedure is more especially adapted are those in which there are excessive pain, loss of appetite and sleep, and great discharge of foul, offensive matter, contaminating the air of the patient's apartment, and rapidly undermining the vital powers. With the aid of anæsthetics, an operation is no longer a source of suffering, and may, in such a condition, if properly performed, be followed by much good, not only freeing the patient from local and constitutional distress, but, perhaps, materially prolonging life by getting rid of a burden which has weighed down both mind and body. Moreover, the recurring disease is not always as bad as the original, although such an event can seldom be foretold with any degree of certainty.

Reproductive Tendency of Malignant Diseases after Operation.—Of the reproductive tendency of malignant diseases, after extirpation, or destruction by the actual or potential cautery, writers have made mention from the earliest periods of medical science to the present time. Hippocrates was fully aware of the fact; and he entered his protest against all operative proceedings, under the conviction that, however early or well executed, they could not possibly afford any permanent relief, or protect the patient against a return of this malady. Similar views have been advanced by nearly all succeeding writers; but a different sentiment is now entertained in regard to removal as a final measure in many cases, provided early and adequate operations are performed.

The period at which relapse occurs varies from a few weeks to several years, the average period being from four to six months. Occasionally it is astonishingly short. In one of my cases relapse appeared in less than three weeks. The original disease, a genuine scirrhus of eight months' standing, occupied nearly the whole of the left breast; the nipple was somewhat retracted, and there was a slight enlargement of one of the lymphatic glands of the axilla, which was removed in the operation. The dissection was performed with the utmost care, and the wound united by the first intention, excepting a little spot at the centre, which remained open and became the starting-point of the new growth. The woman, who was forty-six years of age, died three months after the operation, having endured the most horrible suffering.

When relapse is unusually tardy, the probability is that the original disease was more than ordinarily localized, and that there is no disposition after extirpation to involvement of the general system.

All malignant diseases possess a tendency to relapse after ablation, although not in an equal degree. Encephaloid undoubtedly has it in a far greater degree than scirrhus, and scirrhus than colloid. Melanosis also recurs with great frequency and promptness, and may be placed next to encephaloid in this respect. Even epithelioma often relapses after extirpation, but now and then the part and system continue to be remarkably exempt for years, if not during the remainder of life. Sarcoma, myxoma, and lymphoma also evince a great tendency to local reproduction, the last, indeed, being scarcely inferior in that respect to encephaloid carcinoma.

The reproductive tendency of malignant disease, after operation, is well illustrated in the case of a man, aged thirty-two, who consulted me in April, 1851, on account of a sarcomatous epulis of the lower jaw, first noticed three months previously. The growth was firm, elastic, free from pain, of a pale red color, and attached to the gum and jaw, extending from the ramus to the first bicuspid tooth. Two operations had already been performed upon it, each being followed by rapid relapse. On the 27th of April, I excised the parts, along with the corresponding portion of the jaw. On the 24th of September the patient came again under my care, and I now removed the whole of the new growth, about the size of a pullet's egg, and also about three-quarters of an inch of the anterior extremity of the ramus of the bone, from which the diseased structure seemed to spring. On the 31st of August, 1852, I excised the ramus at the articulation, the disease having

attacked its inferior extremity.   The man remained well until the winter of 1853, when the disease broke out in front of the ear, where it soon formed a tumor as large as a small fist, under the effects of which he rapidly sank.   It is worthy of remark that the general health had all along been pretty good, and that the wound always healed well after each operation.

Epithelioma affords a greater number of non-recurring examples after operation than any other carcinomatous formation.   I have myself had a number of instances of epithelioma of the lip in which there was an entire freedom from disease for years—in some as many as seven, eight, and even ten—and similar good luck has followed some of my excisions of the penis for carcinoma of the head of that organ.   In a case of epithelioma of the lower lip, communicated to me by Dr. Barclay, of New York, the patient survived the first operation seven years, the knife having been employed altogether five times.

In a case of encephaloid sarcoma of the thigh, reported to me by Dr. C. S. Tripler, of the Army, the man did not die until five years after the first operation.   In 1853, I amputated the arm of a gentleman, thirty-five years of age, on account of soft sarcoma of the upper portion of the forearm; the disease had been in progress for nearly twelve months; the tumor was large and well-marked; the wound healed kindly, and life was prolonged for nearly six years, when death occurred from some affection of the lungs and pleuræ, the precise nature of which I have not been able to ascertain.   I am acquainted with the history of a number of other examples nearly equally remarkable.

The recurring tendency of melanotic sarcoma is familiar to every surgeon of experience. Hardly an example of permanent cure by operation is upon record.   A remakable instance of this recurring action came under my notice many years ago, in the practice of the late Professor McClellan, of this city.   The disease had, seemingly, begun in several small subcutaneous tubercles of the abdomen, about the size and color of so many shot, which soon became exquisitely painful, and, gradually bursting through the skin, were at length converted into foul, fungous sores, attended with a highly fetid, sanious discharge.   Many of these tumors were extirpated, some in their crude, others in their open state; but, although the wounds generally readily healed, they were always rapidly succeeded by a new growth in the immediate vicinity of the original.   The man became much emaciated, and finally died completely exhausted, with all the evidences of the melanotic diathesis.

CHAPTER VIII.

SCROFULA AND TUBERCLE.

The term scrofula had formerly a far more limited application than is at present accorded to it.   It was originally employed to designate a glandular swelling of the neck, strikingly resembling the neck of the swine, whence its derivation.   At present, however, it has a much wider signification, including within its range a variety of affections apparently of the most opposite character, and yet in reality essentially alike in every particular.   As meaning the same thing, the words struma and tubercular disease are frequently used.

The affections which may be comprised under this term are pulmonary phthisis, chronic enlargement of the glands of the neck and other parts of the body, hip-joint disease, psoas, lumbar, and chronic abscesses, Pott's disease of the spine, certain forms of follicular ulceration of the mucous membranes, arachnitis, otorrhœa, ozæna, ophthalmia, eczema, and ulceration of the bones.   The fact is, the class of scrofulous maladies is almost endless; for they affect almost every part of the body, and assume almost every form of morbid action.

Scrofula consists essentially of a peculiar state of the system, in which there is a marked tendency to the formation of an inflammatory product known by the name of tubercle.   Attempts have been made from time to time to draw a distinction between tubercle and the state of the system which predisposes to its occurrence.   It is difficult altogether to deny the propriety of this distinction; for there are unquestionably cases which we are in the habit of designating as strumous, where, nevertheless, there is not, so far as can be determined, the slightest tubercular deposit.   There would seem to be

merely a strumous irritation in the part, without the part being in a condition to furnish any product capable of giving rise to tubercles.

There is another distinction, which, however, is fast losing ground, which it is more difficult to reconcile than that just mentioned, the alleged difference between phthisis and scrofula. It would be easy, if a work on surgery were the proper place to discuss the subject, to show the fallacy of this opinion. I have long been convinced of the identity of these diseases, and of the fact that the only actual difference between them depends, not upon any difference in the morbid action, but solely upon the difference of structure, tubercular disease sharing the same fate, in this respect, as ordinary inflammation and as the other atypical formations. A tubercle in the lung is essentially the same disease as a tubercle in a bone or a lymphatic gland, having a similar origin, running a similar course, and producing similar results.

Tubercular disease is of an infectious nature, and is due to the absorption of the softened caseous products of scrofulous inflammation, which excite irritation and proliferation of the cellular elements with which they come in contact, and in that way result in the formation of the tubercle granule. Once formed, submiliary tubercles increase by aggregation, and by their caseous degeneration and softening may act as foci for secondary infection.

The transmissibility of tubercle by inoculation has been confirmed by the experiments of Villemin, Cohnheim, Burdon-Sanderson, and other investigators, and there is reason to believe that tuberculosis may be communicated in the human subject in other ways. Thus Reich has recorded some interesting observations which show that the disease was transmitted by a phthisical nurse to a number of children ; and the risk of contracting the affection by occupying the same bed with a subject of pulmonary consumption, is insisted upon by several authors. Tuberculosis has been produced by feeding the lower animals on tuberculous material ; and Epstein believes that the disease may be transmitted to children by the ingestion of the milk of tuberculous nurses and cows.

Tubercular disease occurs at all periods of life. Sometimes, indeed, it exists as an intra-uterine affection, thus leading to the conviction that it is occasionally hereditary, or that it is transmitted in the very act of impregnation. When it occurs as phthisis, it is most common between the twentieth and fortieth year, and it is remarkable that after the age of puberty it rarely exists in any part of the body without involving the lungs. In children, the disease, considered in a general point of view, is most frequent between the third and tenth year. A vast majority of the cases of scrofulous disease that are met with in the form of coxalgia, Pott's disease, caries of the short bones of the extremities, arachnitis, ophthalmia, otorrhœa, tonsillitis, and chronic enlargement of the lymphatic glands, occur at this period of life, and constitute an immense source of mortality. It is a remarkable fact that adults seldom suffer from external scrofula ; and, on the other hand, it is equally remarkable that children suffer comparatively seldom from consumption, so common among persons after the twentieth year. In old age the disease is rarely witnessed in any form.

Struma is frequently hereditary. The children of consumptive parents are often cut off by the same disease, or they suffer in various parts of the body, as the bones and joints, lymphatic glands, eye, ear, and serous membranes. Whole families are sometimes swept off by it. Occasionally the disease skips one generation, and reappears in another, owing, doubtless, to some temporary improvement in the intermediate offspring.

Tubercle has been observed in nearly all the organs and tissues of the body, the only ones, perhaps, that are exempt from it being the skin, nerves, ligaments, aponeuroses, tendons, and voluntary muscles. The lungs, particularly their summits, are, of all the structures, the most prone to suffer ; then, next in the order of frequency, come the lymphatic glands, then the spleen, serous membranes, and mucous follicles of the alimentary canal, then the bones and joints, and finally the brain, liver, kidneys, testes, and false membranes of the serous cavities. In the lungs and some of the other more vascular organs the external coat of the smaller bloodvessels seems to be the favorite seat of the deposit. Its coexistence in various parts of the body, or its almost universal diffusion, is sufficiently common, and constitutes the so-called strumous diathesis.

The deposit being the result of an infectious inflammatory process, and due to the proliferation of the endothelial cells of the bloodvessels, lymphatics, and of the serous membranes, of the fixed connective-tissue corpuscles, and of the wandering cells, occurs both in the parenchyma and upon the free surfaces of the organs. Hence it exhibits itself in various forms, of which the nodular is by far the most common, the stratiform and infiltrated being, indeed, exceedingly rare. The nodular variety occurs in little masses, from

the size of a millet-seed to that of a pea, of a pale yellowish or grayish color, and of a consistence ranging from that of curds or soft putty to fibro-cartilage, hundreds and even thousands often existing in a very small compass. When very numerous and closely grouped, they sometimes coalesce, so as to form a tumor of considerable size. The stratiform variety of the deposit is most common upon the mucous surfaces, while the infiltrated is met with chiefly in the lungs, around tubercular excavations, and in the lymphatic glands. Whatever shape it may assume, it is always deposited in a soft state, from which however, it passes speedily into the solid form, which it retains for a certain period, generally from six to twelve months, when, becoming softened and disintegrated, the part makes an effort to rid itself of it. These changes are followed by the formation of a cavity, named a strumous abscess, of which the best examples occur in the lungs, bones, and lymphatic glands. The matter is peculiar, being generally of a yellowish, dirty, turbid color, thin, oleaginous, and intermixed with small whitish flakes, very similar to broken-down grains of boiled rice.

Tubercles present certain peculiarities in their histological characters in accordance with their age and the structure of the organ in which they originate. They are, however, usually composed, as is well represented in fig. 73, from Green, of a small-celled lymphoid tissue surrounding giant or multinucleated cells, the branched processes of which are continuous with the adenoid reticulum. The cells contained within the reticulum are round or ovoid, and vary in size from $\frac{1}{2500}$ to $\frac{1}{3500}$ of an inch in diameter. An isolated giant cell with its long processes is shown in fig. 74, copied from the same author.

Fig. 73.   Fig. 74.
Minute Structure of a firm Gray Miliary Tubercle of the Lung in a Case of Acute Tuberculosis.   A Multinucleated Cell from the Lung in a Case of Chronic Phthisis.
Tubercular material, in its crude state, consists almost entirely of albumen, with a small quantity of earthy salts, particularly phosphate and carbonate of lime. Some specimens also contain a little fibrin, casein, extractive matter, and pyine; but the great and pervading substance is albumen, or protein matter.

The microscopical and chemical examinations of tubercle are extremely valuable, inasmuch as they go to show the low grade of its vitality, and its consequent inability to maintain, for any length of time, its existence. The vessels of the tissues in which the new formation originates gradually become obliterated, and, as a result, the nodule undergoes caseous degeneration, which ends in softening and the production of a cavity or an ulcer. Now and then, and particularly when the fatty degeneration is not so marked, the adenoid reticulum is converted in a firm fibroid mass; and dessication and calcification of the caseous material are occasionally met with.

Of the exciting causes of tubercular disease our knowledge is rather conjectural than positive. It may fairly be inferred, however, from the numerous observations that have been made upon the subject, that, when the tendency to the disease exists, anything that produces excessive debility, or an impoverished condition of the blood and solids, may provoke the morbid deposit. The causes which are most likely to bring about this effect are: 1. Meagre and unwholesome food, deficient in fibrinous, albuminous, gelatinous, and fatty qualities. 2. Protracted disorder of the digestive organs, particularly the various

forms of dyspepsia. 3. Exposure to cold, and confinement in damp, ill-ventilated, ill-lighted apartments. 4. Exhausting fevers. 5. Excessive and long-continued evacuations of blood. 6. Severe courses of mercury. 7. Stoppage of habitual discharges, as the menstrual and hemorrhoidal. 8. Protracted mental depression. 9. Syphilis, whether original or inherited. 10. Inordinate sexual indulgence. All these causes act by lowering the vital principle, and diminishing the plastic properties of the blood.

The immediate cause of the disease is inflammation, which regulates not only the quantity, but also the quality, of the deposit. The action is generally of a low grade, and is therefore not characterized by the ordinary phenomena, although it is not the less effective on that account. The reasons which may be adduced in support of this view are the following :—

1. Irritation of the lung, mechanically excited, frequently gives rise to tubercle in that organ, as is occasionally seen in cases of foreign bodies, accidentally introduced through the larynx. In the inferior animals, as the dog and the rabbit, mercury dropped into the trachea often rapidly induces the disease. Miners, needle-grinders, and weavers, habitually exposed to the inhalation of gritty and irritating matter, are particularly prone to phthisis.

2. This view of the origin of the disease is countenanced by the composition of the deposit; for we know of no substance which contains so much albumen, or albumen and fibrin, that is not the product of inflammation.

3. Tubercle bears a great resemblance to lymph, especially the more degraded forms of that substance, and this, as every pathologist is aware, is always the result of inflammatory action.

4. The disease is often developed under the immediate effects of cold, and various other causes which have a tendency to produce congestion of the internal viscera. Indeed, it is well known that dyspeptics, and persons who live upon unwholesome food or in damp and ill-ventilated apartments are peculiarly liable to suffer from this disease.

A close and careful study of scrofula during a half of a century in public and private practice has forced upon my mind the strongest conviction that many of the so-called cases of the disease, as they are brought under our observation, are simply examples of a syphilitic taint of the system in its more remote forms. The influence of the syphilitic poison in establishing a cachectic state of the constitution, and thus deteriorating the blood and solids, has long been recognized, if, indeed, not universally acknowledged, by professional men. A poison like this, so potent, so subtile, so diffusive in its action, and so difficult to eradicate, is well calculated to make the most fearful inroads upon the system, pervading every atom of living matter, weakening the vital powers, and establishing a predisposition to disease, which the slightest causes may readily fan into an open flame. What adds still further to this deterioration of the blood and solids is the harsh and unscientific treatment still so frequently employed, even at the present day, in the different forms of syphilis. Mercury, especially calomel, it is true, is no longer used in the copious and reckless manner so characteristic of the practice of former times. Syphilitic patients are no longer salivated until the tongue protrudes from the mouth, the teeth shake in their sockets, and quarts of saliva are discharged in the twenty-four hours, week after week, draining and exhausting the system, and producing a state of debility often only ending with life itself. The effect of this improved method of treatment has been a marked diminution of the so-called scrofulous affections. Forty years ago strumous disease of the neck was much more common than it is now. At present we seldom meet with those large, hideous glandular swellings, the flattened nose, the deformed palate, and the cadaverous-looking countenance, at that time so frequent, especially among the lower orders of persons, the victims of the joint agency of the syphilitic poison and of injudicious mercurial medication. Such cases have become comparatively rare, at least in this country; and still further improvement may reasonably be anticipated from steady perseverance in the present system of treatment, especially from the use of the iodides in the tertiary form of the disease.

The duration of strumous diseases is too variable to admit of any accurate general statement. Phthisis usually destroys life in from nine to eighteen months; tubercular arachnitis often terminates fatally in a few days; while external scrofula may last for years, and finally eventuate in recovery.

The symptoms vary, of course, according to the nature of the affected structure; but, whatever this may be, there are certain appearances which are hardly ever absent in any case. Thus, whether the disease be seated in the lungs, in a bone, in a joint, or simply in the connective tissue, in the form of a cold abscess, there is always, during its progress,

excessive emaciation; for, with the exception of the glandular viscera, the brain, nerves, and a few other parts, there is hardly any organ in the body that does not, in some degree, participate in the general atrophy. The fat gradually but surely disappears; the muscles are pale, flabby, and attenuated; the connective tissue is deprived of its moisture; the skin is soft and blanched; the hairs grow slowly, and many drop out; the nails are thin, and frequently incurvated; and the bones, although they retain their size, are usually light, and saturated with sero-oleaginous fluid. The blood also is altered. It is impoverished, thin, pale, and deficient in red globules. The clot is unnaturally small and dense, and when the disease is fully established, with a tendency to suppuration, is almost always covered with a buffy coat. The fibrin is not materially changed until softening sets in, when it increases disproportionately in quantity, and so continues until suppuration begins, when it attains its maximum. These alterations are generally very conspicuous in phthisis, psoas abscess, and extensive disease of the lymphatic glands.

Persons who are affected with scrofula, or who are laboring under what is termed the strumous diathesis, exhibit certain peculiarities which may be considered as almost characteristic. These refer mainly to the state of the complexion, the digestive apparatus, and the circulation.

The complexion is generally brunette, and the hair, for the most part, dark, although in both these respects the greatest possible diversity exists. The eyelashes are drooping and of extraordinary length; the pupils are habitually dilated; the upper lip is tumid; the face is pale and puffy; the hands and feet are nearly always cold; the body is unusually impressible by atmospheric vicissitudes; the abdomen is hard and distended; there is a deficiency of muscular strength; and the intellect is dull and sluggish, instead of being sprightly and precocious, as is usually represented. The digestive organs are subject to frequent derangement; the appetite is irregular and capricious; the bowels are either constipated or relaxed, seldom entirely natural; digestion is feeble and imperfect; great annoyance is experienced from flatulence and acidity; and the individual is often a martyr to dyspepsia. Children predisposed to struma are particularly prone to cutaneous eruptions about the scalp, to purulent discharges from the ears, and to chronic enlargement of the tonsils and lymphatic glands.

There is another class of strumous subjects of a state of mind and body almost the opposite of that just described. The complexion is light and florid, the eye blue, the mind unusually active, and the cutaneous circulation very vigorous. The parts of the body which are most liable to suffer, in this form of constitution, are the bones and joints, the eye, skin, and lymphatic glands, particularly those of the neck, consumption being much more rare than in the dark variety.

Scrofulous Ulcer.—Various scrofulous affections of the skin give rise to ulceration, but, perhaps, the most characteristic ulcer of this kind is that consequent upon suppuration of the lymphatic glands of the neck, groin, and axilla. Be this as it may, the features of the scrofulous ulcer are so peculiar as to require distinct notice.

The surface of the scrofulous ulcer is always unhealthy, being coated with rough, aplastic matter, of a pale yellowish or grayish color, hard, and firmly adherent to the subjacent structures. This matter, which possesses none of the characteristics of laudable pus, is often intermixed with disintegrated tubercular substance. In many cases the bottom of the ulcer is formed by altered lymphatic glands, of a reddish appearance, and so much softened as to break down under the slightest pressure; sometimes, however, they are hard, almost of a fibrous consistence, and as if they had been partially dissected from the surrounding parts. In some cases, in fact, they separate, or slough, several perhaps coming away at the same time, or in more or less rapid succession. No healthy granulations exist upon such a sore, unless it is in a healing condition, and even then they form and maintain themselves with great difficulty.

The edges of the ulcer are characteristic. They are of a bluish, purplish, or reddish hue, undermined, hard, jagged, thin and sharp at some points, thick and obtuse at others. Occasionally they are bent in towards the bottom of the ulcer. They are generally remarkably insensible, deeply congested, and incapable of forming healthy granulations. In fact, the skin, having lost its support, is excessively impoverished, and has great difficulty in maintaining its vitality.

The structures around the scrofulous ulcer are generally hard, either from the presence of indurated and diseased glands, or from interstitial deposits; usually, in fact, from both. The skin is red and congested, and not unfrequently also somewhat œdematous, pitting on pressure. The swelling is often great and disfiguring; in short, characteristic of that peculiar appearance from which the disease originally derived its name; the neck, when that is the part affected, strikingly resembling that of the swine.

The scrofulous ulcer may be single, or multiple; variable in shape and extent, and frequently communicating with considerable sinuses. The discharge is ichorous, or thin and whey-like; sometimes thick and yellowish; in either case, apt to be intermixed with the debris of distintegrated glands, flakes of lymph, and broken-down tubercular matter.

The cicatrice left by the healing of a scrofulous ulcer is peculiar. It is of a fibroid texture, very hard, dense, almost crisp, and tightly adherent to the subjacent structures. Its surface is of a purplish hue, more or less depressed, traversed by large veins, and marked by prominent radiating ridges. The surrounding skin is hard and contracted, very much as in the scar of a burn. A long time generally elapses before the new skin becomes soft and pliant, and divested of its unnatural complexion.

Treatment.—The treatment of scrofula, like that of carcinoma, has been exceedingly diversified and empirical, for there is hardly a solitary article of the materia medica that has not, at one time or another, been called into requisition. Even at the present day, when the pathology of the disease is so much better understood, the greatest uncertainty prevails in regard to our therapeutic measures, and the consequence is that few practitioners approach the disease without doubt and misgiving as to the benefit they may be able to confer by their treatment. Strumous affections have always afforded a vast field for the charlatan, and his pretensions have never been more impudently paraded before the public than in our own day. One, if not the chief, reason of this is that so few practitioners really understand the nature of this class of diseases; they seem to forget, or not to know, that they occur in every possible form and under every variety of circumstances, and, that, in order to meet them successfully, it is necessary constantly to vary our remedies according to the exigencies of every particular case. I am certain, from no little experience upon the subject, that the results of our treatment hinge most materially upon a just discrimination of the different states of the system under which these affections occur. To treat every case of scrofula alike, without regard to the condition of the constitution which attends it, is, to say the least, absurd. The disease has no specifics; and I do not hesitate to declare it as my opinion that the indiscriminate use of iodine and cod-liver oil, still so common, has done an immense amount of harm, in so often taking the place of other and more suitable remedies.

It will be sufficient, for practical purposes, to consider scrofulous subjects as being divisible into two great classes, the weak and the vigorous; that is, those who have but little constitutional stamina, and those who, although affected with a strumous taint, are comparatively strong and robust, possessing a ruddy complexion, and an active cutaneous circulation. The latter, undoubtedly, constitute the minority of the cases that come under our observation, but they are, nevertheless, sufficiently common, and so well marked as to be easily recognized by the most superficial observer. Now, to treat these two classes of subjects on the same principle, as is so generally done, is contrary to the dictates both of sound sense and daily experience. While cod-liver oil, iodine, and tonics will perform wonders in the naturally weak, they will be of little avail in dislodging and curing the disease in the naturally robust; and, conversely, while the lancet and tartar emetic will be of immense service in the latter, their employment can scarcely fail to be highly prejudicial in the former. It must not be imagined, however, that one mode of treatment is applicable to every instance of this or of that form of the disease; on the contrary, circumstances constantly arise during the progress of each particular case which imperatively demand a change of remedies, and it is in the knowledge of this fact that the great art of curing the malady lies.

It is well, as a general rule, to begin the treatment with some mild but efficient aperient, to clear out the bowels, and improve the secretions. The course must then be shaped by the peculiarities of the case. If the patient be naturally very feeble, or has become so by protracted suffering, an alterative and tonic course must at once be instituted, as the most likely to meet the indications; but if, on the other hand, he is strong and plethoric, as denoted by the state of his pulse and complexion, much time will be gained, and the structure saved, by the use of antiphlogistics, especially tartar emetic and Epsom salt in the form of the saline and antimonial mixture, properly guarded with tincture of opium. The lancet must be employed with the greatest care; but I am satisfied that it is often of immense benefit in arresting the morbid action, and that it has fallen into too much neglect in the treatment of scrofulous affections. In scrofulous inflammation of the eye, throat, and lymphatic glands, its effects are often marked and permanent. But there is a time when the employment of active measures ceases to be proper, and when they must be superseded by other remedies, similar to those generally applicable in the more common form of the disease. If the depletory system of treatment be carried too far, it

exhausts the vital powers, and thus creates a disposition, in different parts of the body, to deposition of tubercular matter.

Among the various remedies that are employed for the cure of scrofula, iodine may be regarded, in many respects, as the most important. It may be administered alone, or in union with other articles, as potassium, iron, mercury, lead, quinine, barium, and ammonium; and hence much judgment is often required to determine what particular form of it is best adapted to a particular case or form of the malady. As a general rule, it may be stated that, when a purely alterative effect is desired, it may be exhibited by itself, in substance, in tincture, or in the form of Lugol's concentrated solution, consisting of one scruple of iodine and double that quantity of iodide of potassium, dissolved in seven drachms of water. Of this from five to ten drops may be taken every eight hours, in a wineglassful of sweetened water, the dose being gradually increased to fifteen, twenty, twenty-five, or even thirty drops, according to the tolerance of the system.

With the same view, iodide of potassium is not unfrequently administered alone; and, when scrofula is associated with constitutional syphilis, rheumatism, or mercurial disease, it certainly constitutes one of the best forms in which iodine can be exhibited. With whatever intention it be employed, it is proper always to begin with small doses, as four or five grains, if the patient be an adult, gradually increased to ten, fifteen, and even twenty, three or four times a day. The most eligible mode of giving it is in union with some aromatic syrup. Some patients take it very well in hop tea, and when there is much restlessness at night, or nervous irritation, this is perhaps the best form in which it can be exhibited.

When the liver is at fault, when there is a syphilitic taint of the system, or when there is much disorder of the secretions, protiodide of mercury may advantageously be prescribed, in doses varying from the fourth to half a grain, three times a day. The biniodide may be employed with a similar view, but, as it is much more potent, greater caution is necessary in its administration. The dose, which, at first, should not exceed the twelfth or sixteenth of a grain, may be gradually augmented to a fourth or even half a grain, given in the form of pill, or in alcoholic solution.

When an alterant and tonic effect is indicated, nothing can be better than iodide of iron, or iodide of quinia. The former of these articles is one of the most valuable antiscrofulous remedies that we possess, rarely disappointing expectation. In my own practice it has been particularly beneficial in disease of the cervical glands, upper lip, eyes, and joints. I often give it in solution, but more commonly in the form of pill, in union with quinine and opium. If undue vascular action be present, a minute portion of tartrate of antimony and potassium may be added to each dose. In children, who cannot take pills, the best vehicle is syrup of orange peel, or syrup of sarsaparilla.

Iodide of quinia has been advantageously employed in the treatment of scrofulous tumors, in cases where iodine and tonics are indicated, in doses of one to two grains every six or eight hours.

In whatever form iodine is used, whether as a simple or compound, it must be borne in mind that the system should be free from all vascular excitement, and that, after it has been exhibited for a fortnight, it should be pretermitted for several days, when it may be resumed, and given as before. Employed in this manner, it exerts a much happier influence upon the progress of the complaint, and is much less likely to disagree with the stomach and bowels, than when given uninterruptedly. If it acts as an irritant, it must be administered in smaller doses, or in union with opium or hyoscyamus. Great mischief often results from neglect of this precaution.

Barium is another remedy of great value in the treatment of scrofulous disease. It has repeatedly succeeded in my hands when other means have proved inefficient or entirely unavailing; it is particularly serviceable in chronic enlargement of the cervical glands, both before and after the establishment of suppuration. It is chiefly adapted to patients with a languid circulation, a pale, tallow-like complexion, a flabby tongue, indigestion, and cold extremities. Its use is contraindicated when there is inflammatory excitement, or congestion of any important organ. The best mode of administration is the officinal solution of the United States Pharmaropœia, beginning with six or eight drops, and gradually but cautiously increasing the dose to ten, twelve, or fifteen, three times a day, in a wineglassful of hop tea, or half an ounce of syrup of orange peel. Exhibited in large quantities, it is liable to cause nausea, heartburn, diarrhœa, griping, headache, rigors, profuse sweats, and symptoms of mineral poisoning.

Iodide of barium, from its great alterative properties, is worthy of trial in scrofulous affections. The dose is one-eighth of a grain thrice daily, gradually increased to four, five, or even six times that quantity.

Calcium is sometimes employed with advantage, either in the form of iodide or the solution of the chloride, the dose of the former being half a grain, and of the latter from fifteen to thirty drops, three times a day. The medicine is particularly valuable in the treatment of scrofulous affections of the skin and lymphatic glands.

Bromide of iron occasionally answers a good purpose, although, in general, it is very decidedly inferior to the iodide. The best formula is that of Parrish, the average dose of which, for an adult, is twenty drops every eight hours, gradually increased according to the tolerance of the stomach.

There is no medicine which has been more frequently or more extensively employed in the treatment of strumous diseases than mercury. The preparations most commonly selected are calomel, blue mass, corrosive sublimate, and the black sulphuret, or Ethiops mineral. Of these the bichloride is the best. It should be given in minute alterative doses, as the tenth, sixteenth, or twentieth of a grain, three times a day, either in the form of pill, or solution. Thus administered, it yields hardly in efficacy to iodine, and is probably superior to barium. In employing mercury, in any form, care should be taken that the system is properly prepared for its reception, and that it is not carried so far as to induce salivation. If it be found to act as an irritant or excitant in any way, it must at once be discontinued, or exhibited in smaller quantity. Whether mercury produces its beneficial effects merely by correcting the secretions, and thereby improving the general health, or by suspending or modifying the tubercular action, is still a mooted question.

When the disease has existed for a considerable length, and especially when it is accompanied by marked emaciation, great pallor of the countenance, cold extremities, and a small, frequent pulse, great benefit may be expected from the use of cod-liver oil, given in doses of one drachm to half an ounce thrice in the twenty-four hours, in good ale, or along with a little brandy. The value of this remedy is fully borne out by the general testimony of the profession. Although it contains a minute quantity of iodine and bromine, its good effects probably depend chiefly upon its nutritive qualities. However this may be, it unquestionably improves the condition of the digestive organs, and acts slightly upon the urinary and cutaneous secretions. To derive full benefit from it, its use must be continued for a long time, with an occasional intermission, to afford the stomach a short respite, and to prevent the disgust which must necessarily arise from such a remedy when too persistently administered. Experience has shown that cod-liver oil is of no benefit whatever, in this affection, when there is no decided waste of the system, and when the pulse is rather retarded than accelerated.

Whatever remedies may be employed, the closest attention should be paid to the bowels, diet, exercise, and dress. Constipation is counteracted by mild aperients, as blue mass and rhubarb, or, when there is much disorder of the secretions, by a few grains of calomel, followed by a little oil. Active purgation, however, must be studiously avoided, as it will inevitably do mischief by inducing debility. Torpor of the liver must be promptly met by mild mercurials, and acidity by alkalies, of which bicarbonate of sodium, either alone, or in union with a little ginger, is the most valuable. The alkalies were at one time much in vogue in the treatment of scrofula, in the belief that they possessed a kind of specific power, but their influence was evidently much overrated. Emetics are occasionally of service, especially when there is much nausea, depraved appetite, flatulence, and headache.

The diet of a scrofulous patient should be light, unirritant, and nutritious. It should consist principally of the farinaceous articles, with milk or weak tea at breakfast and supper, the latter of which should always be very light, and taken at least three hours before retiring to bed. Coffee, fresh bread, pastry, and, in short, everything of an indigestible nature, must be proscribed. The food should be well masticated, and never used in such quantity as to oppress the stomach. When the strength is much impaired, some of the lighter meats, a little fresh fish, or a few oysters may be taken twice a day, along with a glass of porter, ale, sherry, port or madeira, or, what is better than all, brandy and milk. Sometimes an almost purely animal diet agrees best with the stomach. Many patients are greatly benefited by the free use of whiskey, rapidly becoming strong and fat under its influence. It should be taken repeatedly in the twenty-four hours, in quantities suited to the state of the stomach and system.

As an important auxiliary, exercise claims particular attention. It may be taken on foot, in a carriage, or on horseback, as may be most convenient or agreeable to the sufferer, and should be indulged in whenever the weather admits of it, without being carried to fatigue. In bad weather, the patient may use dumb-bells, or amuse himself in sawing

wood, planing, or anything else to which he may have access. Children should be carried about in their nurses' arms, or in handcarts.

The patient's clothing is worthy of special consideration. He must be warmly clad. Flannel should be worn next the surface, both in summer and winter, the feet should be protected with thick shoes and stockings, and the skin should be maintained in a healthy, perspirable condition by frequent ablutions with tepid water, impregnated with common salt, ground mustard, strong soap, or any other exciting substance.

A change of air is sometimes of vast service, and has been known to be of itself almost sufficient to effect a cure in this disease. The locality selected should be as healthy as possible, and not liable to great or sudden variations of temperature. If the atmosphere be dry, it matters little whether it be cold or warm, provided it do not run into either extreme. A residence near the sea-shore is often of immense benefit; and daily sea-bathing, in the hot summer months, has occasionally produced the most astonishing improvement in the general health.

In the latter stages of the disease, when the patient is harassed with hectic fever and diarrhœa, the treatment must be of a tonic and stimulant character. The diet must be highly nutritious; porter, ale, wine, and milk-punch must be freely used; the bowels must be restrained with astringents; the excessive sweats must be controlled with quinine, elixir of vitriol, or atropia; and sleep must be procured and pain allayed with anodynes.

There is no doubt that the state of the mind is capable of exercising a powerful influence upon the cure of scrofula, especially when seated in the external parts of the body. This may be assumed to be a fact from the astonishing benefit which so often followed the royal touch, a practice which originated in the time of Edward the Confessor, near the middle of the eleventh century, and which continued down to the reign of Queen Anne. The belief in the efficacy of the royal touch seems to have been for a long time almost universal in Britain. It was particularly prevalent in the reign of Charles II., who, in one single year, touched nearly 100,000 persons, who flocked to him from all parts of England, Ireland, Scotland, Jersey, and Guernsey. The practice was generally accompanied by prayers and other religious ceremonies, and particular days and seasons were set apart for its observance. The effect of this singular remedy was variable; in some of the patients a cure followed almost immediately after they were touched; in others, the relief was more tardy, but in the end not the less effectual; occasionally the process was obliged to be repeated; and in some cases the treatment was entirely useless. Richard Wiseman, who was surgeon to Charles II., and a most sagacious observer, must have had great confidence in the efficacy of the royal touch; for he expressly declares that " His Majesty cured more persons of scrofula in one year than all the chirurgeons of London in an age."

The *local treatment* of scrofula merits great attention, although here it can be alluded to only in a very general manner, as each affection comprised under this denomination requires a mode of management in some respects peculiar to itself. The most important topical remedies are leeches, blisters, issues, pustulation with croton oil, tincture of iodine, embrocations, and sorbefacient unguents, especially such as have iodine for their bases, as the iodides of mercury, lead, potassium, iron, barium, cadmium, and zinc. Leeches are often of immense service; and, as to counterirritants, they can rarely ever be entirely dispensed with. Of the various sorbefacient applications none is entitled to a higher rank than the tincture of iodine, either pure, or as I generally prefer, considerably diluted with alcohol. It is used as in ordinary inflammation, and often exerts a powerful influence upon the progress of external scrofula, especially of the joints and cervical glands. Blisters, too, are a valuable means for relieving local congestion, modifying capillary action, and removing morbid deposit. If the part affected be a joint, rest, long and faithfully continued, will be necessary, if, indeed, not indispensable. If abscesses form, they must be opened, with the precaution, if possible, of excluding the air, unless they are situated very superficially, experience having shown that such ingress is highly prejudicial, not on account of anything noxious in the air itself, but because of its tendency to cause decomposition of the contents of the sac, and, consequently, violent reaction, or hectic irritation. The swelling is attacked in its most depending part, the knife being introduced in a valve-like manner, and the opening immediately closed with adhesive strips, supported by a compress and roller. The practice of permitting such accumulations to continue until they have seriously impaired structure, or caused intense suffering, cannot be too pointedly condemned.

When the enlarged glands obstinately resist treatment, they should be excised, provided they are sufficiently accessible, and there is no serious internal disease forbidding

interference. An operation is particularly indicated when the morbid growths press upon important neighboring structures, or when they are a source of great deformity, as when they are situated in the neck, under the chin, or about the angle of the jaw. The dissection is often tedious and bloody, especially when a large chain of glands has to be removed, and is then very liable to be followed by erysipelas and other bad consequences. When the glands have undergone caseous transformation they should always be removed with the view of preventing tubercular infection of other organs and tissues.

The scrofulous *ulcer* must be treated rudely at first, and gently afterwards. The undermined edges are cut away with the knife or scissors, and the surface is thoroughly touched with the dilute acid nitrate of mercury, the solid nitrate of silver, or sulphate of copper, the application being repeated every other day until there is an appearance of healthy granulations, when milder means, such as opiate cerate, or the dilute ointment of nitrate of mercury, take its place. If disintegrated glands are present, they are removed with the knife, or destroyed with the Vienna paste ; for so long as they remain, no substantial progress can be made towards a cure. Sinuses are traced out with the bistoury, unless they involve important structures, when stimulating injections, or the seton, must be used instead. Valuable aid will often accrue in these cases from the daily application of the dilute tincture of iodine to the surface immediately around the ulcer.

CHAPTER IX.

VENEREAL DISEASES.

THREE distinct affections are included under the term venereal. They all arise primarily from impure connection ; they are all contagious ; they all produce only their like ; and they may all coexist in the same person. Of these maladies, gonorrhœa is a catarrhal inflammation of the mucous membrane of the urethra or of the vagina ; chancroid is the local contagious venereal ulcer ; while syphilis is a specific disease, the initial lesion of which is chancre, or the constitutional contagious ulcer. The first of these affections will be considered in the chapter on the diseases of the male genital organs.

1. CHANCROID.

By the word chancroid is understood a disease which, in some of its features, resembles chancre, but differs from it in the fact that it is essentially a local contagious venereal ulcer ; whereas chancre is always the first manifestation of contamination of the system by the syphilitic virus. This distinction, which was for a long time held in doubt, is now generally, if not universally, admitted by the most distinguished and reliable syphilographers. It had, as will be seen, by a reference to the previous editions of this work, disturbed my own mind during nearly the whole of my professional life ; and it has only been within the last few years that, in consequence of the accumulating light of modern observation by men of the greatest opportunity, and the most reliable skill and judgment, in different parts of the world, my doubts have been finally removed. This perplexity was shared by many writers, and was caused, in some degree at least, by the fact that there are two kinds of chancres, a hard and a soft ; the latter, although very uncommon, being equally infecting with the former. Chancroid is supposed to have existed from the earliest ages of society, whereas chancre or true syphilis is said to be of comparatively modern origin, our first knowledge of it, as is alleged, being coeval with the discovery of this continent by Columbus in 1492. How erroneous this assertion is, it would be easy to show by an abundant array of facts gathered from the history of the various nations of the earth ; but as this is not the place to discuss the subject, it will be sufficient here to state that the first scientific and truly trustworthy attempt to separate the two diseases, or, in other words, to establish the doctrine of dualism, now so generally held, was first distinctly enunciated, in 1852, by Bassereau, of Paris. It is not surprising that this doctrine should have met with much opposition ; many of the best minds in the profession arrayed themselves against it ; but this opposition has gradually disappeared, and it may be boldly asserted that the number of unicists at the present day is as small as it is

uninfluential. It should not be forgotten, in this connection, that hardly one hundred years have elapsed since the doctrine of the identity of gonorrhœa and syphilis was successfully controverted.

What the precise nature of the poison of chancroid is is still an enigma. That its virulence resides mainly, if, indeed, not exclusively, in the pus globules of the secretion of the ulcer or sore whence it is derived, seems to be sufficiently established by clinical observations, as well by arguments derived from analogy. Rollet ascertained experimentally that, if the secretion of chancroid be freed from its globules by filtration, the remaining substance is innocuous. It is apparently owing to this fact that the virus, instead of entering the system and thus making an impression upon the constitution, is arrested in the lymphatic glands of the groin, where, sooner or later, it is capable of provoking suppuration and ulceration, the pus of which is, in its turn, highly inoculable. In fact, the sore thus produced is, in all essential particulars, a chancroid. Beyond this the matter does not travel; it is here that its action is arrested, and, however frequently it may affect the genital organs, it never infects the system, or occasion what are called secondary symptoms, such as are so constantly witnessed in syphilis. There may be, and indeed frequently is, irritative or inflammatory fever, but such excitement is entirely independent of the absorption of poisonous matter into the general system, as is invariably the case with the virus of syphilis; and the same is true of the pus that is furnished by the inflamed connective tissue around a suppurating gland, the product of the pus of chancroid. However abundant the fluid may be, it does not poison the constitution, so as to give rise to secondary phenomena, even supposing, as is undoubtedly the case, that some of the secretion occasionally enters the system; in other words, the secretion is devoid of contaminating power; its effects are purely local. Another peculiarity of this matter is that an individual who has once been the subject of it is at any time, if exposed to its contact again, liable to its influence; the virus of syphilis, on the contrary, rarely affects the same person twice, the impression made by it upon the system being, like that of smallpox, scarlatina, and kindred maladies, generally permanent or ineradicable.

It has been conjectured that the virulence of chancroidal matter is due to the presence of low animal or vegetable organisms, but if such parasites exist, they have never been satisfactorily demonstrated. The fact is, no mode of examination hitherto employed has succeeded in revealing its intimate nature. Its admixture with vaccine, gonorrhœal, or syphilitic matter does not necessarily impair its power; frozen and then thawed, it is still inoculable. Inclosed in a hermetically sealed tube, Ricord inserted it successfully at the end of seventeen days. Its potency, says Bumstead, is not destroyed by dilution with six to ten times its quantity of water. It is rendered innocuous, however, by exposure to a high temperature, and by admixture with alcohol, alkalies, and acids.

It has been supposed that the matter of chancroid may, under certain circumstances, arise spontaneously, and subsequently retain, for an indefinite period, its inoculable qualities. In support of this view, writers have cited the experiments of Pick, in which he inoculated simple, non-venereal matter of inflammatory origin, as that, for example, of acne, scabies, or pemphigus, upon syphilitic persons, and obtained well-formed pustules, the contents of which retained their nocuous properties through several generations. These results have since been verified by other observers; and Dr. Edward Wigglesworth, of Boston, has gone a step further by showing that the matter of acne and scabies, inoculated upon a perfectly healthy individual, will produce similar effects. Interesting as these experiments undoubtedly are, they fail, in my opinion, to prove that such fluids are capable of causing a true chancroidal disease; we might as well assume that simple, non-venereal pus could give rise to smallpox and other zymotic diseases. The only philosophical conclusion is that the secretion of chancroid is the invariable product of a specific inoculation.

It is still a mooted question whether chancroid can be transmitted from man to the lower animals. Hunter and Ricord performed numerous experiments upon dogs, asses, cats, rabbits, guinea-pigs, and pigeons, without propagating the disease in a solitary instance. On the other hand, Auzias Turenne, Diday, and other observers declare that they have succeeded in inducing the disease with matter of this kind in a number of the inferior animals. Fortunately, the solution of this question, one way or another, is of no practical moment.

The relative frequency of chancroid and chancre is worthy of brief notice, although, in a practical point of view, it is of little or no value. Of 10,000 cases of these affections observed by Puche at the Hôpital du Midi, 8045 were chancroids, and 1955 were chancres. Le Fort, on the other hand, finds that of 1789 cases, 951 belonged to the

former class, and 838 to the latter. Dr. Hardie, of the British army, ascertained that the proportion of chancroids to chancres in 303 cases was about two to one. It is highly probable that the relative frequency of the two affections is modified by local and consti- tional causes, as the peculiar character of the exposures, and the condition of the system at the time of the inoculation. Military surgeons have noticed that chancroids prevail in one garrison, and chancres in another; and it is not unlikely that similar occurrences take place among the residents of towns and cities.

The most common sites of chancroid are the genital organs, not that they possess any special aptitude over certain other parts, but because these structures from their peculiar situation are most frequently exposed to the contact of its peculiar secretion. All the mucous outlets of the body are more or less obnoxious to it; and, if matter of this kind be inserted underneath the epidermis in any region of the body, a specific pustule and ulcer will be certain to arise. Fournier has constructed a table of 445 cases of chancroid, in 347 of which the gland or prepuce was involved; various parts of the penis suffered in 70, the meatus in 11, and the interior of the urethra in 5. Debauge has published the statistics of 206 cases of this disease as occurring in women. In 78 of the cases the fourchette or navicular fossa was affected, the labia in 19, the nymphæ in 16, the urethra in 21, the lower part of the vagina in 24, the neck of the uterus in 1, the margin of the anus in 23, and the perineum and the groove between the nates each in 5.

A chancroidal ulcer may gradually wear itself out, or continue variously modified for an almost indefinite period, now stationary, now better or worse. As healthy granula- tions spring up the discharge sensibly lessens, the areola of inflammation, if there was any, disappears, and although the ulcer contracts under the influence of new tissue extending from the edges towards the centre, unless there has been uncommon destruction of tissue, such an ulcer seldom, if ever, leaves any trace to mark its former existence.

The rarity of chancroid on and within the uterus is worthy of special notice, as it is in singular contrast with the occurrence of chancre in those sites. A similar remark applies to the lips, tongue, and mouth, structures in which chancroid is exceedingly uncommon, while chancre is by no means infrequent, and may generally be readily in- duced by auto-inoculation, or by the insertion of matter into the affected person himself, or by hetero-inoculation, as when the secretion is transferred from one individual to another.

If the secretion of a chancroid be inserted just beneath the epidermis, a reddish blush will form around the puncture in twenty-four hours, which is converted into an inflamed areola on the second day, at the centre of which a vesicle forms, and is soon converted into a pustule. In the course of a few days the latter breaks, and discloses a circular ulcer with abrupt, sharply cut, and undermined edges, and a non-indurated, grayish, uneven floor, which secretes a tolerably abundant purulent fluid.

The chancroid, whether it results from inoculation or contagion, has no period of incu- bation properly so called, as is always the case with chancre. Indeed, well-marked symptoms often appear within the first twenty-four hours. Of 666 examples of the dis- ease observed by Le Fort, 510 attained their full development by the end of the first week. Early development is especially to be looked for when the virus during an impure inter- course is brought in immediate contact with an abraded or ulcerated surface. Then the fire is at once kindled into full activity. It is different when the offending matter has to work its way through a sound mucous crypt or an unbroken surface, inasmuch as this always retards its progress.

The chancroidal ulcer is generally more or less rounded in form, especially when it takes its rise in a mucous or sebaceous gland; when it begins in an abrasion, it is often very irregular, and not unfrequently exhibits the appearance of a fissure or groove. In the male it is most common at the free margin of the prepuce, or at, or just behind, the corona of the penis. Several chancroids often spring up simultaneously, as in fig. 75, from Cullerier, and others are liable to form during the progress from fresh inoculation, or the mere contact of their own secretions with the surrounding parts. In one case under my charge, in a woman, upwards of fifty years of age, I counted not fewer than forty sores of this kind, from the size of a mustard-seed to that of a three-cent piece, on the vulva and perineum. The surface of the chancroidal ulcer is generally superficial, flat, uneven, and coated with a grayish, whitish, or dirty, drab-colored deposit, evidently spoiled lymph. It has frequently a ragged, worm-eaten appearance. When the sore is seated on the head of the penis, its edges are steep and rather abrupt, as if it had been punched out, or sharply defined with a knife; but on the prepuce they are usually overhanging, sloping, or shelving, more or less ragged, and less closely identified than in chancre with the sur-

rounding structures.   The base of a chancroid is entirely free from induration, except in very rare cases in which irritating applications have been used, followed by an increase of morbid action and a deposit of plasma.   It is worthy of note that every ulcer of this kind is an inflammatory ulcer.

Fig. 75.

Multiple Chancroids.

A chancroidal ulcer generally manifests a disposition to spread, or to enlarge its area; and hence, especially in persons of a dilapidated constitution, occasionally runs into phagedenic action.   It furnishes an abundance of purulent fluid, which is highly contagious, and, therefore, readily inoculable, thus accounting, as already stated, for the multiplication of sores during the progress of the disease, one ulcer being superadded to another simply by the dissemination of the secretion over the contiguous surface. The sores are followed, in about one-third of the cases, by bubo, the disease being usually limited to one of the superficial glands of the groin, which, becoming gradually inflamed and swollen, suppurates, and eventually forms an ulcer, the matter of which, like that of the original sore, is of a highly inoculable character, and capable, in turn, of producing a chancroid if implanted into skin or mucous membrane.   Finally, a chancroid never contaminates the system, or gives rise to secondary and tertiary symptoms.

Well-marked febrile commotion sometimes attends this disease, but this, as a rule, is the case only when it is followed by more or less serious complications, when the inoculation has occurred during serious impairment of the general health, or when the attack is of an unusually virulent nature.   Ordinarily the constitution takes little or no cognizance of the local affection, any more than it does of a boil or common sore.   The pain is generally insignificant, except when the sores are very numerous or unusually large, or accompanied by severe swelling and other evidences of high inflammation.

Chancroid as now described is liable to be modified in its appearances, progress, and modes of termination by local and constitutional circumstances, among which the most important are the want of cleanliness and the degree of the concomitant inflammation, the habits of the individual, the state of the general health at the time of the inoculation, and the supervention of intercurrent diseases.   The influence which these several causes are capable of exerting is, in many cases, so great as to change the whole outward features of the existing ulcer; hence those numerous divisions and subdivisions of chancroid which have tended so much to embarrass the progress of our knowledge.   It is impossible for this disease to observe the same uniform course in every instance; alterations are inevitable, and must often occur despite the utmost caution both of the patient and his attendant.   In this respect, a chancroid holds the same relation as an ordinary ulcer, presenting one appearance to-day and another to-morrow; now highly inflamed, and now almost free from irritation; at one time in a healing condition, and at another ready to commit the most destructive ravages.   Out of these appearances, or varieties of appearances, have sprung the so-called inflammatory, diphtheritic, phagedenic, and sloughing chancroids, with several others which it is unnecessary here to mention.   Such occurrences constitute complications of disease rather than species and varieties, for they are liable to take place in all sores, whatever their character, whether simple or malignant, specific or common.   There is reason to believe that the specific poison may sometimes undergo such a radical change as to adapt it, in an especial manner, for the production of these differences in the appearances of the local affection.   Promiscuous intercourse with badly diseased women, particularly if they are foreigners, and receive the embraces of a considerable number of men in rapid succession, would seem to be a powerful predisposing cause of these accidents.   It was observed by the surgeons who accompanied the British army into Portugal that many of the soldiers who had connection with the native prostitutes suffered severely from phagedenic and gangrenous ulcers, while the residents of the country experienced very little trouble, and usually soon recovered from the effects of the disease.   The French soldiers, during Bonaparte's campaign in Egypt, suffered in the same manner.   Similar phenomena are frequently witnessed in the inmates of the houses of ill-fame in crowded cities.   Thus, in London, in Swan Alley, a narrow lane, celebrated as the residence of the humblest class of prostitutes, half starved, badly clothed, nearly constantly intoxicated, and having frequent intercourse every day with filthy lascars and other vagabonds, many of the cases of chancroid assumed the worst possible type, running rapidly into phagedenic action, and often causing frightful ravages and
even loss of life. Examples of a like kind came under my observation in this city, in 1827, 8, and 9, in the Philadelphia Almshouse, and in the numerous brothels which then existed among the low blacks and whites south of Pine Street. What may be termed international chancroid, the result of sexual intercourse between civilized people and the low, degraded Indians of Mexico and South America, is, in every sense of the term, one of the very worst types of this disease, the poison acting with much greater virulence than under ordinary circumstances.

All chancroids are *inflammatory* affections, and it is, therefore, only when the concomitant action assumes a grave type that it can be regarded as unnatural. Under such circumstances, the characteristic symptoms consist of inordinate pain and swelling of the parts more directly involved in the disease, accompanied by an increase of discoloration, and an unhealthy aspect of the ulcer, which is the seat of a thin, ichorous discharge, more or less abundant, and generally a good deal irritating. Morbid erections are frequent, the prepuce is disposed to be œdematous, and the whole organ, especially the anterior extremity, appears to be enlarged. When the inflammatory action transcends certain limits, it may pass into gangrene or destructive ulceration, as occasionally happens in common ulcers of the leg, and from similar causes, especially from the excessive use of ardent spirits, loss of sleep, bad air, an impoverished diet, and improper courses of mercury. Or, the overaction may be brought on by a plethoric state of the system, and a neglect of the requisite depletion. I have seen gangrene and phagedenic ulceration of the genital organs of both sexes occur at a very early period, in consequence, apparently, merely of too active a course of treatment soon after the establishment of the disease, and such cases are sometimes characterized by extraordinary rapidity of progress, the suffering parts being, as it were, overwhelmed by the disease.

Phagedena is a rare complication of chancroid, especially in the better classes of subjects; it is analogous, in its worst forms, to hospital gangrene, and is most liable to show itself in persons whose constitution has been ruined by intemperance and other debilitating influences. As already stated, it sometimes occurs as an endemic, and is then probably induced by a foul state of the atmosphere, as when the disease breaks out in the crowded wards of public institutions; or by some peculiar modification of the chancroidal poison, greatly heightening its virulence, as when it takes place in soldiers after having cohabited with foreign prostitutes. The morbid action deports itself variously; in general it extends rather slowly, but continuously, gradually but effectually eroding the parts, and thus widening the breach as well as deepening it. Or, it may be that, as one portion of the chancroid heals, another spreads. Or, the action may be very acute, extending with extraordinary rapidity, and committing excessive ravages in an almost incredibly short

Fig. 76.

Acute Phagedena, burrowing beneath the Integuments of the Penis.

time. Or, lastly, the erosion may be conjoined with gangrene, the textures dying both molecularly and in mass. The phagedena may begin soon after the appearance of the chancroid, or it may manifest itself, as is most generally the case, at various periods of its progress. It may occur upon any portion of the genital organs, but is most common upon those parts of the mucous surfaces which are most plentifully supplied with follicles. In the male it is most liable to appear in the gutter behind the head of the penis, or at the point of reflection of the prepuce. The under surface of the penis, at the side of the frenum, is another favorite site, and when chancroid occurs here it is almost certain to destroy this fold of mucous membrane. The appearances of phagedenic chancroid are illustrated in fig. 76.

The phagedenic complication is sometimes followed by grave hemorrhage, the erosive action laying open, it may be, an artery of considerable size, as the dorsal artery of the penis, from which blood may issue in such quantities as to induce severe, if not fatal, exhaustion. The scarlet hue of the fluid and the saltatory character of the stream will at once indicate its source. In some cases it oozes from the ulcerated surface at many points, as water from a sponge.

Gangrene, as a consequence of chancroid, is more common on the prepuce than on the head of the penis, and, what is remarkable, the upper portion is more frequently affected than the lower or lateral. Occasionally both the head and foreskin are attacked simultaneously, or, if one suffer first, the other is soon attacked also, and in this manner the whole organ may gradually be involved, dropping off perhaps ultimately near the scrotum, or at its attachments to the pubic bones. The occurrence of gangrene is announced by a blackish spot, preceded and accompanied by a burning, smarting pain, and by an aggravation of all the other inflammatory symptoms. The system is extremely feverish, the

pulse is frequent and irritable, sleep and appetite are impaired, or, more commonly, entirely destroyed, and the patient is often slightly delirious. When the prepuce alone suffers, the whole of it may slough off, or, what is not unusual, it may be perforated at one or more points, the largest opening perhaps admitting the head of the penis, as in fig. 77. A common effect of gangrene, consequent upon chancroid, no matter where situated, is the destruction of the specific poison, thus effectually preventing inoculation of the lymphatic glands of the groin, provided that had not previously taken place.

The Sloughing Sore, the Prepuce being almost destroyed, and the Head going.

Chancroids sometimes assume a *serpiginous* form, the erosive process, as the term implies, creeping about in different directions, generally in circles or semicircles, one portion of the sore being perhaps cicatrized or partially healed while another is steadily advancing at the opposite point. The ulcer, although generally superficial, occasionally penetrates to a considerable depth, and, as its course is usually chronic, it often results in serious mutilation. Its surface, incrusted with grayish, greenish, or drab-colored lymph, is bathed with ichorous fluid, its edges being steep, ragged, and more or less everted. The serpiginous form of chancroid is most common in persons of a strumous constitution, especially if they are predisposed to phthisis, and herpetic affections. It is generally remarkably obstinate, and sometimes undermines almost the entire skin of the penis nearly as far as the pubes, from which it may extend into the groin, abdomen, perineum, or thigh, forming narrow, superficial tracks, which retain their specific character during the whole period of their existence, however protracted.

When the sore is incrusted with lymph, it constitutes what the French syphilographers have called the *diphtheritic* chancroid; such an occurrence is very common in all ill-conditioned specific ulcers upon the genital organs, and is always denotive of an unusually irritable and inflamed condition of the part, the action of which altogether transcends the healthy limits, nature being incapable of converting the deposit into granulations, and so throwing it off in the form of a slough, or as an effete substance.

Diagnosis.—The diagnosis of chancroid is often difficult and sometimes impracticable, particularly in its earlier stages, before the disease has assumed its more distinctive features. The affections with which it is most liable to be confounded are chancre, herpes, eczema, balanitis, and simple excoriations, fissures, or abrasions, the result of friction and other accidents.

The diagnosis between chancroid and chancre will be fully discussed in the section devoted to the consideration of the latter. Here it will suffice to state, in general terms, that chancroid is characterized, in contradistinction to chancre, by its rapid development, its abundant secretion, the absence of induration, and its tendency to multiplicity, one sore being frequently followed by another simply from the inoculable nature of the discharges.

Herpes is an eruption on the prepuce and head of the penis of little vesicles, hardly as large as the head of a pin, occurring in groups, closely set together, of a whitish color, and resting upon a florid base, with which they form a striking contrast. They are most frequent on the inner surface of the prepuce, in persons of red hair and tender skin, and often appear in successive crops, none of which, however, last longer than six or eight days. Characterized by a sense of itching and a slight serous discharge, they manifest little disposition to extend, and usually promptly yield to very simple treatment. The resulting ulcer is always free from induration.

Chancroids rarely put on the appearance of herpes. The only approach to it is where the ulcers are seated in the mucous follicles, but even then their circular form and excavated character will always serve to distinguish them from common sores.

Eczema is also an eruptive disease, but the little vesicles are more minute and diffused than in herpes, and there is also usually a greater amount of local irritation, the parts being swollen, hot, red, and itchy. When the vesicles burst, a thin, watery fluid escapes, succeeded by the development of small, delicate scales. The affection is apt to become chronic, and then little crevices generally form, increasing the irritation, and furnishing an acrid, sero-purulent, sanious, or ichorous discharge. Eczema is most common on the prepuce, and is often particularly conspicuous at its free border. A careful examination of the affected structures, the history of the case, and the existence of eczema in other parts of the body, will always lead to a correct distinction between this disease and chancroid.

An inexperienced practitioner might possibly mistake an incipient balanitis for a

chancroid, but no one who has ever seen the two diseases could commit such an error. In balanitis the inflammation is generally widely diffused, often, indeed, over the whole surface of the prepuce and head of the penis, and the discharge is not only profuse, but of a thick, muco-purulent nature from the very commencement. There is no circumscribed ulceration as in chancroid, and, indeed, little or no tendency whatever to destruction of tissue. These characters will always serve to prevent the disease from being confounded with chancroid, which invariably presents itself as a distinct and well-defined ulcer.

Simple ulcers, abrasions, or excoriations are liable to appear upon the prepuce and head of the penis, and may, unless great caution is exercised, be mistaken for chancroids. They may proceed from a great variety of causes, as want of cleanliness, friction of the pantaloons, injury received during copulation, and intercourse with filthy females, especially such as are habitually the subjects of profuse and acrid discharges. However induced, such ulcers are always very superficial, and display no disposition to extend in depth, although they may spread considerably in diameter. The secretions which attend them are of an ichorous character, and they are usually surrounded by an inflammatory border, which is seldom the case in chancroid. The most important diagnostic feature, however, by far, is that such ulcers always very promptly disappear under the most simple remedies, attention to cleanliness, with cooling lotions and a mild aperient, generally sufficing to effect a cure in a few days.

Epithelioma is sometimes, but rarely, mistaken for chancroid. The absence of ulceration and discharge in the earlier stages of the disease, and the tuberculated, warty, or cauliflower-like appearance of the sore after the occurrence of ulceration, together with the peculiar quality and quantity of the secretion, the fluid being always of a thin ichorous or sero-purulent character and much more copious and fetid than in chancroid, are the most trustworthy diagnostic phenomena. The history of the case usually affords additional light. Most of the epithelial growths in fact, occurring upon the prepuce and head of the penis, reveal their own secrets.

The site, size, shape, appearance, and course of chancroid, considered separately, afford no reliable diagnostic evidence; but, collectively, are of great importance as means of discrimination. Thus, mere site and size are of no consequence, because a chancroid may, like a common sore, occur on any portion of the penis and be very diminutive, as when, for instance, it occupies a mucous follicle; but if, in addition to this, the ulcer is found to be excavated, to have a foul, diphtheritic bottom, to pursue a chronic course, and to resist the ordinary means of cure, it is quite impossible to mistake its character; we conclude that it is chancroidal, and nothing else.

The history of the case often affords valuable information. If the patient is a married man, or if he has any other motive for concealment, he will be likely to deny that he has had impure connection, and even insist upon it that the sore on the penis is non-specific. Under such circumstances, it is not necessary to try to convict him of falsehood; the surgeon examines the parts, and if he finds any suspicious-looking ulcers, he will very naturally conclude that they are venereal, and this opinion will be strengthened by the very denials of the patient, especially if he is noted for his gallantries. Young unmarried men usually treat their attendants with entire candor, generally specifying with great particularity the time of the impure connection, and evincing no little anxiety to afford them all the light they can, with a view of settling the diagnosis. We must not, therefore, on the one hand, believe that a man has not been exposed to infection simply because he says so; or, on the other, take it for granted that every sore that may be found upon the penis is of a specific nature.

Finally, in all cases of doubt the groins should be examined with reference to the existence or non-existence of bubo. In the ordinary non-specific affections, above described, glandular enlargement is extremely rare, and it usually appears early in the attack, the bubo being small and always comparatively transient. In chancroid swelling of the groin occurs only once in every third or fourth case, and is invariably attended with more or less pain, aggravated by exercise and pressure, and tending to suppuration. In chancre, the swelling is indolent, non-inflammatory, and persistent; it rarely appears before the twelfth or fifteenth day from the impure contact, and very seldom passes into suppuration or ulceration.

When the above means of diagnosis fail, as they seldom will, if proper care be used, the only other resource is inoculation, a small quantity of the suspected matter being inserted, upon the point of a lancet, into the skin on the inside of the thigh. If the oper-

ation is gradually followed by a vesicle, and this, in turn, by a pustule, with a well-marked areola, there can be no doubt whatever respecting the true nature of the disease. Inoculation, if properly executed, cannot deceive, and is, therefore, after all, the only true and reliable test, although there are few surgeons of experience who will not, as a general rule, be able to determine the diagnosis without its aid.

The prognosis of chancroid is always favorable in the milder forms of the disease occurring in persons of sound constitution. In neglected cases, however, or cases complicated with high inflammation, the disease often assumes a very serious character, causing great suffering, local and constitutional, and, perhaps, more or less extensive loss of substance. In former times when chancroid was a much more severe affection than it is at the present day, it was not uncommon, especially in persons of depraved constitution, rendered so by intemperance, debility, exposure, or the use of mercury, to witness gangrene of the affected organs, large portions of which occasionally sloughed off. Gangrene of the prepuce is a possible occurrence in phimosis attended with great œdema. In chancroid of the urethra stricture is almost inevitable under any circumstances. In chronic or neglected cases the disease may continue for months, or even years, causing more or less suffering and more or less mutilation.

Prophylaxis.—If the old adage, " an ounce of prevention is worth a pound of cure," is any where applicable to diseases, it is emphatically so in the venereal affections. The susceptibility to the disease varies, as is well known, very greatly in different persons, some being remarkably prone to suffer from the slightest contact of the specific matter, while others, less delicately organized, escape with impunity. When a man has exposed himself to suspicious intercourse, the penis should immediately be washed with soap and water, special care being taken to cleanse the margin of the prepuce, the groove at the neck of the penis, and the parts around the frenum; for it is at these points, more particularly, that the virulent matter is most liable to effect a lodgment. Women should use a large syringe, charged with a strong solution of alum, common salt, chlorinated sodium, or permanganate of potassium, with which the vagina should be thoroughly cleansed, the fluid being thrown up with considerable force against the uterus with a Davidson's syringe. The nymphæ, labia, and perineum must be washed with a sponge. A very excellent lotion for preventive purposes, much used by the prostitutes of Bordeaux, is composed of half an ounce of alum, and of fifteen grains each of sulphate of copper and sulphate of protoxide of iron, dissolved in a quart of distilled water, with the addition of one drachm and a half of compound aromatic alcohol.

In some of the larger cities of Europe, especially on the continent, the occupants of houses of prostitution are regularly inspected once, if not twice, a week, with a view to the prevention of the spread of these diseases, and it is to be regretted that the practice has not been introduced in this country, considering the immense benefit which, if it were properly carried out, it would confer upon the public, by the insurance of greater cleanliness, and the consequent diminution of the frequency of the miseries entailed by these maladies. It is a fact of not a little diagnostic value that, while a chancroid is, as a rule, always easy of detection with the speculum, a chancre, owing to its small size and illdeveloped character, is readily overlooked.

Treatment.—The treatment of chancroid in its early stages, or before the lapse of ten days, if there are no decided contraindications, growing out of the existence of severe inflammation, must be conducted with the threefold object of shortening the duration of the disease, destroying the contagious principle of the secretion, and preventing the formation of a bubo. As excision of the sore is rarely of any avail, an attempt to accomplish these objects should be made by means of escharotics. The one most generally selected is nitrate of silver, cut to a very delicate point, and inserted into the ulcer, or broken vesicle, where it is held until the infected tissues are brought thoroughly under its influence. The objection to this substance is its insufficiency; for, whether it act simply as a neutralizer of the poison or as an escharotic, it is equally certain that it is generally unreliable, and it should, therefore, never be used in a disease of such a serious nature. The article to which I have long given the preference, on account of its superior efficacy, is the officinal solution of the acid nitrate of mercury, applied either pure or variously diluted, according to the exigencies of each particular case. A good average strength is one part of the acid to double the quantity of water, applied with a piece of soft wood, the end of which is smooth and well rounded off. Such a contrivance is much better than a probe wrapped with lint and cotton, as the fluid can thus be brought in contact with the infected surface in a more concentrated and efficient manner. In order to prevent the solution from diffusing itself too widely, the part should previously be well

wiped, and immediately after bathed in pure water, or some weak alkaline lotion. The most suitable dressing is an emollient poultice. One free application of the acid generally suffices.

When acid nitrate of mercury is not at hand, almost any of the acids may be employed, especially the carbolic, nitric, or hydrochloric. Some surgeons use caustic potassa, while others give a preference to the Vienna paste. Ricord recommends a powerful caustic, composed of sulphuric acid and powdered charcoal, united in the proper proportions to form a semisolid mass. Of this carbo-sulphuric paste, as it is called, a thin layer is applied to the chancroid and the parts immediately adjacent, upon which it soon dries, forming a black, adherent crust, which, on dropping off, as it usually does in eight or ten days, leaves a healthy, granulating sore, rapidly followed by cicatrization. The objections to the carbo-sulphuric paste are the extreme pain which it produces, and its tendency to spread too widely over the sound tissues. Of late years I have found that pure carbolic acid is the least painful and one of the most valuable of the escharotics.

Abortive measures are justifiable only in the very earliest stages of the disease, before the supervention of marked inflammatory action. When this stage has been passed such treatment cannot fail to do harm by increasing the local irritation. Mild measures alone are proper in such a condition. From neglect of this precaution, which cannot be enforced with too much emphasis, many a sore on the genital organs that would, if properly managed, disappear in a few days, is often protracted for weeks, if not months, to the great detriment both of the part and system. Young and inexperienced practitioners are very prone to fall into this error; they think they cannot do too much, and the consequence is that they fret and worry the sore until it places itself, so to speak, in a state of open rebellion, resisting all measures, local and constitutional, that may be adopted under the delusive hope of effecting its cure. Rest and attention to diet are of inestimable value in every case. Strict confinement to the house is not always necessary by any means, but any thing like excitement, physical or mental, should be scrupulously guarded against; the bowels should be moved from time to time with cooling laxatives, and no animal food, unless absolutely called for by the exhausted condition of the patient, should be permitted. This kind of indulgence never fails to retard the cure, and often leads to serious complications, and yet, strange as it may seem, it rarely engages the surgeon's attention. If the secretions are disordered, as evinced by the coated tongue, the depraved appetite, bad taste in the mouth, or distressing headache, an active mercurial cathartic may be administered; but for no other reason should mercury ever be employed in the treatment of an affection which, as is now well known, never contaminates the constitution in the sense that syphilis does. Febrile excitement is kept in abeyance with the neutral mixture, or antimonial and saline preparations, with the addition to each dose of a few drops of tincture of aconite. Anodynes are given to relieve pain, induce sleep, and prevent reaction; in a word, the whole treatment is conducted upon strictly antiphlogistic and soothing principles.

Cleanliness is of the utmost importance in every case of the disease, and is best secured by frequent immersion of the penis in warm water, containing a little common salt, acetate of lead, or chlorinated sodium. If the chancroid is concealed by a tight and irritated prepuce, the syringe is freely used, as it will be impossible to effect retraction to an extent sufficient for ordinary ablution. In the intervals of these local baths, which, while they favor cleanliness and comfort, contribute materially to the reduction of the inflammation, the ulcer should be kept constantly covered with lint, wet with a weak solution of tannic acid and opium in compound spirit of lavender, yellow wash, sulphate of copper, or acetate of lead. Tannic acid and opium are most excellent remedies, exerting at once an astringent and soothing influence, greatly promotive of healthy action. They form the principal ingredients of the aromatic wine, so much used in the French hospitals, and their efficacy has been well attested both in public and private practice everywhere. The yellow wash is also a very valuable agent, but to obtain all the good which it is capable of yielding, it should be employed very weak, as one-eighth of a grain of the mercury to the ounce of lime-water, the strength being increased if necessary on account of the slow progress of the case. The officinal preparation is much too strong and irritating. I have frequently derived great benefit from the ointment of nitrate of mercury, diluted with eight, ten, or twelve parts of simple cerate, and applied either alone or in union with tannic acid and opium. In fact, there is no remedy which has done better or more efficient service in my hands than this in the treatment of simple chancroid. Powdered iodoform, sprinkled on the sore, is highly praised by many practitioners as an excitant to healthy granulations; but its odor is so penetrating and disagreeable as to make it objectionable in

private practice. This disagreeable feature may be overcome by employing the remedy in the form of an ointment composed of one drachm of iodoform, two drachms of balsam of Peru, six drops of oil of peppermint, and five drachms of cosmoline. Employed in this way it constitutes an excellent application, especially when the sore is seated upon the integument.

There is one important rule which applies here with as much force as in the case of common ulcers, and that is to vary the dressings whenever they are found to become a source of irritation, or cease to be beneficial, making them now weaker, now stronger, adding new ingredients, omitting old ones, or changing the remedy altogether. Much of the success, in every case, will depend upon the care with which this rule of practice is carried out.

When the parts begin to granulate, the simplest dressings generally suffice, such as opiate cerate, or ointment of red oxide of mercury, diluted with eight, ten, or twelve times its bulk of cosmoline, or merely a bit of dry lint carefully interposed between the contiguous surfaces. The latter application often promotes cicatrization with remarkable rapidity.

When the head of the penis is swollen and painful, it must be kept constantly buried in an emollient poultice, made of powdered elm bark or ground linseed, and frequently changed. Or, instead of this, warm water-dressing may be used, its efficacy being increased by the addition of laudanum and acetate of lead. The best vehicle for such dressing is cotton wool, in which the organ, properly elevated, and maintained at rest, should be completely buried.

Constitutional treatment is too important to be overlooked, however simple the sore. Perfect quietude of mind and body is indispensable. The effects of any disturbance of this kind always manifest themselves promptly in the aspect of the sore and the character of the secretions. The diet must be plain and simple, animal food and stimulants being carefully avoided; the bowels are kept open by cooling purgatives; and, if need be, free use must be made of saline and antimonial preparations. Venesection will rarely be required, and then only in very plethoric subjects. If the local trouble is considerable, leeches may be applied to the groins or to the inner surface of the thighs, the bites being well covered, when the flow of blood has ceased, with collodion, in order to prevent their inoculation from the accidental contact of chancroidal matter. Leeches should never be applied to the penis itself, much less to the parts immediately affected, as their secretions could hardly fail to come in contact with the little wounds, and so propagate the disease.

When chancroid is accompanied by severe *inflammation*, as denoted by the swollen, discolored, and painful condition of the parts, and the feverish state of the system, antiphlogistic means should at once be vigorously employed. Active purgation, light diet, the neutral mixture, and the use of antimonials, with absolute rest in the recumbent posture, cooling, anodyne, and mildly astringent lotions to the ulcer, and an emollient poultice or warm water-dressing for the head of the penis, constitute the chief remedies in such an emergency, and must be carried to an extent compatible with the powers of the system. Pain and morbid erections are relieved with opiates and bromide of potassium, administered in full doses. By these means the disease is soon brought under subjection, when it is to be managed in the same gentle manner as the milder forms of chancroid already described.

Chancroid of the frenum is almost invariably followed by perforation of that fold, and, in such a case, the cure is always greatly expedited by its prompt division, the raw surface being immediately cauterized with carbolic acid.

When the ulcer assumes a *phagedenic* character, with a tendency to spread more or less rapidly both in depth and diameter, the principal addition to the treatment, required in chancroid complicated with undue inflammation, consists in the increased amount of opium employed to soothe the part and system, which are generally excessively irritable in this variety of morbid action, and can only be successfully quieted by the most liberal use of this article. If the skin be hot and arid, the pulse excited, and the face flushed, the opium should be combined with antimony, or some cooling diaphoretic, so as to produce a decided determination to the surface. The diet and bowels must receive due attention; all stimulants must be avoided; and the mind and body must be maintained in the most tranquil condition.

The local applications should all be of the blandest kind, consisting of warm water-dressing or emollient poultices, and of lint steeped in mucilage of gum arabic, or an infusion of elm bark, with the addition, to each ounce of fluid, of two or three drops of

nitric acid and one drachm of the vinous tincture of opium. If the disintegrating action is very rapid, the ulcer should be covered with iodoform, or be freely mopped with a weak solution of acid nitrate of mercury, or, touched with solid nitrate of silver, its surface being kept constantly covered in the interval with the medicated lotion just mentioned. In some cases nothing arrests the erosive tendency so speedily as a weak solution of sulphate of copper, in the proportion of about one grain to the ounce of water, with the addition of four to six times that quantity each of tannic acid and opium. When the action is obstinate, immersion of the parts in hot water is very efficient in arresting its progress and in relieving pain.

The phagedenic form of chancroid, however, does not always occur in the strong and robust; the system may be, and often is, in an adynamic condition, requiring tonics and stimulants instead of depressants. The constitution, degraded perhaps by long suffering, by starvation, and by all kinds of intemperance, must be brought up with quinine and iron, porter, ale, or milk punch, a generous diet, and change of air, particularly if the patient is the inmate of a crowded and ill-ventilated hospital. The dissipated and enervated residents of large cities are particularly prone to suffer from phagedena during the progress of chancroid, and it is, therefore, impossible to be too cautious in regard to the employment of depletory measures. What is needed in such a state of the system is perfect tranquillity of mind and body, as secured by the liberal exhibition of anodynes, and a better condition of the blood, to enable the part to institute a more salutary action.

If *gangrene* set in, the treatment must vary according to the concomitant state of the system, independently of any consideration growing out of the presence of the specific virus. The question should simply be, is the action of the system too high or too low? If the former, antiphlogistics will be indicated, and should be promptly employed, although not without a certain degree of reserve, lest the powers of the constitution should suffer from the effect, and thus encourage the spread of the disease. Depletory measures, if used at all, must be used warily. The excitement may only be apparent, not real; and may, consequently, shortly subside, either spontaneously, or under very simple remedies. Most likely the action is typhoid from the beginning, or, if not, it soon will be; hence, instead of a depletory, a corroborative course will be necessary, similar to that in ordinary gangrene in other parts of the body, the chief reliance, so far as constitutional means are concerned, being upon quinine, iron, ammonia, brandy, camphor, and opium, with milk and rich animal broths. The use of potassio-tartrate of iron, in doses of ten to twenty grains, repeated four or five times in the twenty-four hours, has been greatly lauded in this form of the disease; but, judging from the results of my own experience, it possesses no advantages whatever over the sulphate and tincture of the chloride, so much employed in all anemic states of the system.

To arrest the gangrenous action, and promote the separation of the eschars, the affected structures should be freely painted with dilute tincture of iodine, and wrapped up in an emollient poultice, medicated with laudanum and acetate of lead, Goulard's extract, or what is superior to either, a saturated solution of potassio-tartrate of iron, while the dying tissues are well mopped with the acid nitrate of mercury, or brought under the full influence of carbolic acid. If any constriction exist, as that produced by a tightened and retracted prepuce, it must promptly be relieved with the knife. The detachment of the sloughs may be promoted artificially, or, if not too large, be intrusted entirely to nature's efforts; at all events, all harsh interference must be carefully avoided. Fetor is allayed with chlorinated sodium, permanganate of potassium, or other means.

The sloughs having separated, the next object is to favor the development of healthy granulations; for which the most available remedies will be found to be the nitric acid lotion, with tincture of opium, the ointment of the balsam of Peru, the aromatic wine, or the dilute ointment of acid nitrate of mercury, with warm water-dressing or an emollient cataplasm, as a general covering to the affected structures. A lotion composed of five to ten grains of potassio-tartrate of iron to the ounce of water is often very beneficial in improving the condition of the sore.

The *serpiginous* chancroid is generally an obstinate and troublesome sore, for the cure of which one of the most efficient local remedies is a saturated solution of potassio-tartrate of iron, applied upon lint. In very rebellious cases it is sometimes necessary to use strong lotions of nitric, carbolic, or hydrochloric acid, or even to sear the surface of the ulcer with the actual cautery, with a view of changing its condition. The undermined and partially devitalized edges must be removed with the scissors. Constitutional treatment is indispensable. Chalybeate tonics, cod-liver oil, a generous diet, exercise in the open air, or a residence at the seaside, will greatly assist recovery.

In the *diphtheritic* chancroid the most efficient remedy for reducing the inflammation is the warm water-dressing, or an emollient cataplasm, medicated with opium and sugar of lead, the sore being touched once a day with solid nitrate of silver, or brushed over with a weak solution of acid nitrate of mercury. Under this management, aided by suitable constitutional means, the sore soon assumes a more healthy action, followed by the development of florid granulations, and a gradual tendency to cicatrization and a final cure.

The *indolent* chancroid, or chancroid attended with deficient action, generally depends upon some defect of the system, by correcting which the ulcer will speedily assume a healthy appearance, throwing out florid granulations, furnishing thick, laudable pus, and cicatrizing along its margins. Or it may be that the obstacle is of a strictly local nature, occasioned by want of cleanliness, by an undermined condition of the sore, or, by the presence of a thick, semiorganized, and firmly adherent layer of lymph. Whatever the cause may be, it should, if possible, be promptly rectified; the constitution, if at fault, is suitably improved, and every effort is made to promote the granulating process. Particular attention is given to cleanliness, the thickened and shelving edges are trimmed off with the scissors, and the incrusted surface, freely cauterized with nitrate of silver, nitric acid, or acid nitrate of mercury, is kept constantly covered with blue ointment or some stimulating lotion. The best internal remedy generally is the tincture of chloride of iron in doses of twenty drops four times a day, in union with quinine. The potassio-tartrate of iron is also a valuable agent, and may be given in doses of ten to fifteen grains every eight hours, dissolved in water and syrup of orange peel.

Any *hemorrhage* that may arise during the progress of chancroid must promptly be arrested; the patient may already be much exhausted by previous suffering, and a slight drainage of this kind might, therefore, prove exceedingly prejudicial. When the blood issues from an open orifice, the vessel should at once be secured by ligature, acupressure, or compressing forceps, a sufficiency of tissue being included in their bite to insure safe maintenance. If, on the contrary, it proceeds from numerous points, the ordinary styptics, as alum, or, what is better, Monsel's salt, with a full dose of opium and aconite to control the heart's action, will generally suffice for its speedy arrest.

The morbid *erections* which so often accompany chancroid, and which generally so much impede the reparative process, must be treated in the same manner as in gonorrhœa; by the liberal use of anodynes by the skin, mouth, or rectum, and by soothing topical applications, either warm or cold, as may be most grateful to the part and system. If hemorrhage be present, they must be controlled at all hazards, on account of their tendency to tear open the bleeding vessels.

Phimosis, complicating chancroid, must not be interfered with, unless it act constrictingly, threatening destruction of the prepuce and of the glans by mortification. In this event, the parts must be freely divided upon the grooved director, the edges of the incision being immediately cauterized with carbolic acid or acid nitrate of mercury, and coated with a layer of collodion to prevent inoculation. In ordinary cases, the tightened foreskin is permitted to retain its place, cleanliness and medication of the ulcer being effected, as already stated, by means of the syringe.

Paraphimosis is occasionally present, perhaps to a perplexing and even dangerous extent. The constriction produced by it may be such as to cause excessive œdema of the prepuce, and great engorgement, if not severe swelling of the head of the penis, inducing a condition which, if not speedily relieved, may eventuate in extensive gangrene. These effects may occur whether the chancre be situated on the head or on the retracted prepuce, and, for the reason just mentioned, always demand prompt attention. An attempt should be made to restore the parts by manual effort, aided by anæsthesia, to give the surgeon more perfect command over his movements. This failing, the only alternative is to divide the stricture, and to keep the wound well coated with collodion, to prevent further inoculation.

Chancroids in women.—The structures which are most liable to suffer from chancroids in woman are the vulva, labia, nymphæ, vagina, urethra, and the vicinity of the clitoris. The inferior third of the vagina is more frequently affected than the middle or upper third, and the uterus suffers least of all. A very common site of chancroids is the fourchette, its dependent position favoring the contact of the contagious secretions, no matter what parts of the genital organs may be involved in the specific disease. For a similar reason, the perineum, the anus, and even the buttocks are occasionally covered with chancroids. In the case of an elderly woman, previously alluded to, I counted forty chancroids upon the perineum.

Chancroids upon the female genitals affect almost every variety of number, size, and shape. Generally they are multiple, from autoinoculation of the secretions; of small dimensions, and of an irregularly rounded or ovoidal shape; sometimes they occur in the form of fissures, and at other times they coalesce or run into each other, forming thus ulcers of large size. However this may be, they seldom, except in women of dilapidated constitution, reach to any great depth, but are usually superficial, although they always furnish an abundance of thick, purulent, and highly inoculable matter. Great pain and swelling are often present, especially when the chancroids occupy the labia, the lower part of the vagina, or the anus and perineum. Chancroids of the urethra often cause excessive suffering and extensive destruction of tissue. Occasionally the vesico-vaginal septum gives way, and stricture of the anus, and even of the rectum is by no means an uncommon occurrence. Chancroids in the female genitals are liable to be followed by phagedena, gangrene, and other serious effects, precisely as in the male; buboes, are, however, less frequent. Ulcers of the uterus are generally difficult to cure, and are more apt to take on phagedenic action, often destroying large portions of the neck of the organ, and even extending some distance up the canal.

The diagnosis can only be determined by the history of the case and by careful ocular inspection. The rapid development of the sores, their multiple character, and the profuse, inoculable secretion, and the existence of more or less pain, form important elements in the discrimination of the disease. In case of doubt, inoculation may be practised.

In the treatment of chancroids of the female genitals, the same general rules are applicable as in the corresponding affections in men. Absolute rest in the recumbent posture, active purgation, saline and antimonial preparations, opiates, diaphoretics, the warm bath, and light diet, constitute the most appropriate remedies in ordinary cases. The most important topical means are frequent injections of hot water, or of hot water medicated with alum, chlorinated sodium, or carbolic acid; the application, especially if there be overaction threatening the occurrence of phagedena or gangrene, of weak solutions of acid nitrate of mercury; and, above all, isolation of the affected surfaces with plugs of lint or cotton, medicated with aromatic wine, lotions of tannic acid and opium, yellow wash, or some slightly stimulating ointment. Pain is allayed, and rest secured with anodynes in full doses, repeated as often as may be necessary. Tonics and other supporting measures are of course necessary in exhausted states of the system.

CHANCROIDAL BUBO.

Bubo essentially consists of an enlargement of the lymphatic glands of the groin, and is the result of the transference of the virus of the original sore to the latter situation. Hence it is capable of furnishing a secretion similar to that by which it was itself produced. An open chancroidal bubo is, in fact, nothing more or less than a chancroidal ulcer, resembling in every essential particular a chancroidal ulcer of the genital organs. Like the latter, it is wholly of a local nature, or, in other words, incapable of contaminating the system. The chancroidal bubo is present only in about one-third of the cases of chancroidal disease, whereas the true syphilitic bubo, or glandular enlargement, is a universal sequence of inoculation with the syphilitic virus; the latter never tends to suppuration, is strictly indolent, and is characterized by a remarkable degree of induration, seldom noticeable, as a prominent feature, before the end of the tenth to the fifteenth day from the time of the impure contact. Moreover, the syphilitic bubo is always followed by constitutional disease, or, more correctly speaking, is an evidence that the system has already been invaded.

The chancroidal bubo is usually limited to one or at most two glands, although others may become involved during the progress of the disease, not by direct inoculation but by an extension of the inflammation which always accompanies the inoculation. The relative proportion of bubo to chancroid has not been definitely settled; but it will be sufficiently near the truth if it be put down at one case in every three, three and a half, or four. An active, open state of the primary ulcer, and the smallest conceiveable amount of inflammation in the structures immediately around are, other things being equal, the conditions most favorable to the development of the disease. Large or numerous sores attended with an abundant discharge of pus also materially contribute to the occurrence. On the other hand, the absorption of the specific virus and its transmission by the lymphatic vessels to the groin are accomplished with great difficulty when the parts are overpowered by disease. The occurrence of phagedena or gangrene early during the progress of the primary ulcer is sure to act as a preventive.

The bubo generally occurs on the same side as the primary sore. Thus, if the ulcer exist on the right side of the penis, the right groin will be the one to suffer, and conversely. Occasionally an exception to this rule is met with, depending, probably, upon an interlacement of the lymphatic vessels, those of the right side passing over to the left, and the reverse. A bad form of bubo sometimes occurs at the root of the penis, or upon the pubes, caused by the presence of an infected gland. Now and then a bubo is developed in each groin, especially when the chancroid is situated upon some part of the middle line, as the frenum or the upper surface of the penis.

The chancroidal bubo is much more frequent in men than in women, owing to the differences in the arrangement of the lymphatic vessels, those of the former passing in a much more direct manner than those of the latter from the seat of the disease. In chancroid of the uterus and the upper part of the vagina bubo is uncommon, and the same law obtains in regard to chancroid of the urethra in the male.

An opinion was at one time extensively prevalent that a bubo may form in the groin without the intervention or antecedence of chancroid, from the direct absorption of the specific poison from a mucous or cutaneous surface. It was and still is maintained by some that such an effect is possible, because, as is alleged, virulent bubo occasionally occurs without any evidence whatever of having been preceded by primary ulcers. It is assumed that the matter in which the poison is entangled, or held, as it were, in solution, may be absorbed by the mucous or even the cutaneous surface of the penis in the same manner as morphia, atropia, and other articles of the materia medica, and that, being subsequently conveyed by the lymphatic vessels to the groin, it is capable of infecting its glands in such a way as to form a true chancroidal bubo. Hence, the disease has been called the primary non-consecutive bubo, or, to use a French phrase, bubon d'emblée. The existence of this variety of bubo was admitted by several of the older writers on venereal diseases, especially by Astruc and Swediaur; Hunter also believed in it, and it was at one time dwelt upon at much length by Ricord and his disciples. Many of the most experienced practitioners, however, in all parts of the world, positively assert that they have never met with it, and, as for myself, I am sure that no instance of the kind has ever fallen under my observation.

Varieties.—Bubo, like chancroid, is susceptible of a great variety of forms. Thus, it may, after having made a certain amount of progress, remain stationary, perhaps even for several months, manifesting no decided disposition either to advance or to recede. In another class of cases the enlarged glands, taking on inordinate inflammatory action, pass into *suppuration*, the matter usually collecting in a solitary abscess, of an ovoidal shape, from the volume of an almond up to that of a goose's egg. When the disease assumes this form, it generally runs its course with considerable rapidity, being characterized by severe constitutional disturbance, such as rigors, fever, and headache, and by intense local suffering, the pain being of an aching, throbbing character, the swelling great, the heat excessive, and the discoloration of a dusky livid red. If the matter, which is generally of a thick, yellowish appearance, intermingled with blood and cellular sloughs, is not promptly evacuated, it is apt to burrow among the neighboring tissues, causing extensive sinuses, which it is often extremely difficult to heal, and which occasionally lay open most important structures. In neglected cases, such an abscess may, on the one hand, pass high up over the abdomen, and, on the other, low down upon the front of the thigh. Dr. Lente has reported a case of virulent bubo in which the matter perforated the abdomen, and induced fatal peritonitis. In a case mentioned to me by Dr. J. M. Barton, upwards of a quart of pus was discharged through the rectum, the patient, notwithstanding the most extensive suppuration of the groin, thigh, and abdomen, making eventually a good recovery. Whenever the quantity of matter is unusually large, it may be assumed that it is mainly furnished by the connective tissue in which the affected glands are wrapt up, and not by these bodies themselves.

When the contents of the abscess have been discharged, whether spontaneously or otherwise, the disease assumes the name of an open, *ulcerating* bubo, a state in which it may remain, with very little change, for an almost indefinite period. The discharge from such a sore, which is always situated above Poupart's ligament, or partly above and partly below, and which inclines from above downwards and inwards, may partake more or less of the character of laudable pus, or it may, as is most common, be thin, ichorous, and irritating, the quantity varying from several drachms to upwards of an ounce in the twenty-four hours. It retains its specific properties until cicitrization is completed. The edges of the sore exhibit very much the same appearances as those of a common ulcer; thus, they may be very steep, and ragged; everted, inverted, or undermined; thick or

thin; pale, reddish, dusky, or purple. The bottom is usually incrusted with a dirty, greenish, or yellowish pultaceous substance, with here and there a small, fiery-looking, exquisitely sensitive granulation. Sinuses often extend from the main ulcer in different directions, and it is not uncommon, when the destruction has been at all extensive, to see some of the affected glands lying in a partially detached state at the bottom of the sore, perhaps adhering merely by a few shreds of connective tissue.

An ulcerated bubo may take on *phagedenic* action, extending more or less rapidly in different directions, especially in persons of an unhealthy constitution. This epiphenomenon may show itself soon after the swelling has been laid open, or not until after the lapse of several weeks or months. It is usually characterized by severe pain, by a thin, profuse, sanious discharge, and by a foul, pultaceous state of the sore, along with an irritable condition of the system, want of appetite and sleep, and disorder of the alimentary canal.

Finally, a virulent bubo may run into *gangrene :* sometimes before ulceration sets in, but usually not until afterwards. Such a termination is most liable to occur in the lower classes of patients, the inmates of cellars, prisons, almshouses, and other filthy places, and often produces the most frightful ravages, causing extensive destruction of the skin and connective tissue, as well as, in some cases, of the muscles of the abdomen. The symptoms are generally very severe and the disease often proves fatal, the sufferer, meanwhile, forming a most loathsome and disgusting object.

Diagnosis.—Chancroidal bubo is liable to be confounded with bubo from other causes, and hence it is by no means always easy to determine the diagnosis, desirable as it is that there should be no mistake upon a subject of such practical moment. There are a few points in connection with these classes of swelling which are deserving of attention as means of discrimination. In the first place, the surgeon must carefully consider the history of the case. A chancroidal bubo seldom comes on before the end of the second week from the primary disease, and in many instances, indeed, not until a much later period. In the common bubo, the swelling ordinarily supervenes within a short time after the application of the exciting cause. Thus, a boil upon the nates, or a corn, bruise, or other injury of the toe, is usually followed by a bubo during the first three or four days after the commencement of the local affection. Secondly, useful information may be obtained from a consideration of the duration of the swelling. A chancroidal bubo usually lasts a number of weeks, often, indeed, several months ; an ordinary bubo, on the other hand, generally promptly disappears with the cause that induced it. Thirdly, the chancroidal bubo often suppurates and ulcerates ; the common bubo seldom, and then only or chiefly in persons of a scrofulous and broken constitution. Fourthly, the matter of the chancroidal bubo is always inoculable ; of the common, never. Finally, the chancroidal swelling is always situated above Poupart's ligament, or partly below and partly above ; the non-specific usually below, and generally affects a greater number of glands.

The syphilitic bubo generally appears at the same time as the induration of the base of the initial lesion, and involves a number of glands, which are distinct, freely movable upon one another and the surrounding tissues, and densely hard. It rarely suppurates, and its secretion is not autoinoculable.

The scrofulous bubo occurs only in persons of a scrofulous diathesis, mostly in children, prior to the age of puberty. It commonly affects a considerable number of glands simultaneously, and they remain enlarged for a long time, being very hard and lobulated, and slowly tending to suppuration. The matter is of a yellow-greenish hue, and collects in several little abscesses, which, bursting, leave ill-conditioned ulcers, with thin, bluish, undermined edges, and a thin, sanious, irritating discharge, destitute of inoculable properties. The bulk of the swelling is usually situated below Poupart's ligament, at the upper and inner part of the thigh ; and traces of strumous disease generally occur in other parts of the body.

Treatment.—The treatment of bubo must be conducted upon the same general principles as that of the primary sore, of which, as already stated, it is simply another form. If the disease be seen early, before there is much inflammatory action or any decided tendency to suppuration, the abortive treatment will come into play, consisting of the free application of tincture of iodine, and of concentrated compression, either with a truss, a piece of lead, a bag of fine shot, a series of linen pads, or, what is better than anything else, layers of wet sponge frequently renewed, and secured with the spica bandage. There are few cases of incipient bubo which can resist the combined influence of these remedies, if properly managed. If the compression prove painful, it must be moderated, or temporarily pretermitted. Occasionally the treatment is advantageously preceded by the application of leeches placed around the periphery of the affected glands.

If the disease has already made considerable progress, iodine and compression will probably prove insufficient, and then more active measures will be required. Of these, the most efficient is the formation of an eschar upon the most prominent portion of the swelling by means of the Vienna paste, applied as in making an ordinary issue, or a solution of bichloride of mercury, in the proportion of twenty grains to the ounce of alcohol. The skin having previously been elevated by a small blister, a compress, wet with the lotion, is firmly bound upon the raw surface, and retained for two hours, when it is replaced by an emollient poultice or warm-water dressing. The pain produced by this aplication is excessive, and hence the paste usually deserves the preference, especially as the mercury does not possess any special therapeutic advantages. The new action created by the caustic neutralizes or overwhelms the preëxisting, and rapidly destroys the specific disease.

When suppuration is threatened, or inevitable, it should be expedited by the usual means, especially emollient poultices, aided by recumbency and a relaxed position of the lower extremity. As soon as fluctuation is observed, the parts must be freely divided, even if the matter be deep-seated, in order to give full vent to the confined fluid. A tent is kept in the opening to prevent closure of the edges. Two incisions should always be made, one in the direction of Poupart's ligament, and the other perpendicularly, or in the direction of the linea alba, to afford thorough drainage. The operation is sometimes attended with considerable hemorrhage, chiefly, however, of a venous nature, and, consequently, easily arrested by pressure and quietude. If troublesome, the cavity should be packed with lint, wet with Monsel's solution. When the suppurative process is very slow and imperfect, the most appropriate application is a large blister, retained sufficiently long to produce thorough vesication, and dressed with an emollient poultice. When the accumulation of pus is very large, it has been proposed to effect its evacuation, not by incision, but by the aspirator, or by numerous punctures, on the ground that it would be less destructive to the integument than the more common operation. I have not, however, found this to be so in my own practice. On the contrary, the skin and connective tissue are generally so much detached and impoverished as to render it impossible to preserve them with any reasonable prospect of ultimate reunion. Hence, I am always in favor of a free division; nor do I hesitate afterwards to remove such portions of integument as may seem to act obstructingly to the reparative process by overhanging the surface of the ulcer, and thus interfering with its medication. If sinuses form, they must be laid open, early and freely, in the usual manner; or, if they are very deep and tortuous, injected with some stimulating lotion, tented, and compressed. Fungous granulations are repressed with escharotics, as sulphate of copper or acid nitrate of mercury, or, what is better, the scissors. Loose glands are removed with the scoop or the knife. If the constitution is impaired by protracted suffering and confinement, tonics and change of air will be required; and in all cases proper attention must be paid to the diet, bowels, and secretions. If phagedena or gangrene supervene, the same line of treatment will be demanded as under similar circumstances in the primary disease.

II. SYPHILIS.

SECT. I.—GENERAL CONSIDERATIONS.

The term syphilis is applied to a disease which, commencing in the genital organs in the form of a sore of a specific character, invades the lymphatic glands of the groin, the cutaneous and mucous tissues, and finally also the bones, cartilages, fibrous membranes, and viscera, leaving upon each and all of them, as well as upon the system at large, a peculiar and distinctive impress. These different parts, however, do not all suffer at one and the same time; on the contrary, it would seem to be necessary that the poison upon which the infection depends should lie for a certain period in the tissues in which it has been deposited, in order to enable it to prepare itself for further action. Thus, in the first instance, the operation of the poison is limited to the genital organs and the lymphatic glands of the groin. After having lingered here for some time, varying, on an average, from six to seven weeks, the cutaneous and mucous surfaces begin to suffer; and at a still later period, generally from six to eighteen months, the bones, cartilages, fibrous membranes, and viscera are attacked. In this manner are produced three distinct groups of syphilis, known, respectively, as primary, secondary, and tertiary. To these has lately been added another, the quaternary, in which the disease is seated, mainly, in the nervous

system and the viscera, as the brain, lungs, heart, liver, spleen, kidneys, and testicles, the latter of which may be regarded as external viscera.

It is not my intention here to enter into an account of the history of the origin of syphilis; such an undertaking, besides involving an immense amount of research, ethnological, literary, and biblical, would be entirely out of place in a treatise of this description, limited as it is to the practical details of surgery. I may remark, however, that, in my opinion, it is great folly to regard the disease as of modern origin. If the records of antiquity could be fully explored, it cannot be doubted that we should discover the most satisfactory and irrefragable evidence of the existence of syphilis in the most remote periods of society, now aggravated and now kept in abeyance, according to the habits and morals of the various races of mankind, and the nature of the climate of the countries in which they dwelt. If the history of the inner life of Sodom and Gomorrah could be laid open to our scrutiny, it would furnish a page to the history of prostitution as loathsome and disgusting as any afforded by the vilest and most depraved cities of the present day, either in the Old World or in the New.

Experiments performed by Turenne, Diday, and others, conclusively show that while chancroid may be propagated from man to the inferior animals, as the monkey, cat, rabbit, and horse, and from these back again to man, in no instance has inoculation with the virus of a chancre succeeded in producing a similar local affection or constitutional involvement.

The disease invariably arises from inoculation with a peculiar *poison*, known as the poison of syphilis or chancre. Of the precise nature of this poison all that is known is, that, when inserted into the tissues, it engenders a disease similar to itself, the resulting sore yielding a virus, in every respect, identical with that which furnished it in the first instance. Like the poison of smallpox, it is a peculiar poison, capable of reproducing itself, and of multiplying itself by zymosis. The smallest inconceivable atom, brought in contact with an appropriate surface, speedily develops a disease which, if permitted to progress, may occasion the most horrible consequences, both local and constitutional, and so contaminate the solids and fluids as to render it transmissible from the parent to the offspring. As a little yeast may impregnate a large mass of dough, and cause a ferment that shall affect every particle of gluten entering into its composition, so a little syphilitic virus, so minute as to be utterly inappreciable by our senses, may affect the whole system, and poison every avenue of life and health. Zymosis having fairly commenced, it is impossible, in any case, unless proper means be adopted to counteract it, to say when it may cease, or what may be its ultimate effects.

The specific property of the syphilitic virus is not destroyed for a number of weeks, if the secretion with which it is combined is preserved in a well-corked vial; resembling, in this respect, the virus of vaccinia and variola. Sperino relates a case where the matter, dried upon the point of a lancet, was successfully inoculated at the expiration of seven months. It is rendered inert by chemical agents, and also by gangrene of the tissues infected with it.

The virus does not seem to have any particular predilection for age, sex, temperament, or occupation; all are alike liable to be affected by it. Previous disease does not prevent its action. It produces its peculiar impression most readily when applied to a clean ulcerated surface, an abrasion, or a recent wound; but inoculation may take place independently of these circumstances, simply from the introduction of the virus into a mucous follicle, which thus serves to entangle and retain it until its structure is brought thoroughly under its influence. When the part to which the virus is applied is perfectly healthy, several days may elapse before it is impregnated; or it may even escape entirely, the matter which contains it either not being able to penetrate its surface, or being wiped off before the occurrence of absorption. For the same reason a person thus situated may communicate the poison to another so as to give rise to a chancre, while he himself experiences no ill effects. Such a result not unfrequently occurs in women, from the entanglement of syphilitic matter in the folds of the mucous membrane of the vagina, from which it is afterwards transferred to the virile organ in the act of copulation.

The syphilitic virus may be communicated in various ways; first, and most commonly, by sexual intercourse; secondly, by kissing or sucking, through the agency of a mucous tubercle on the lip, tongue, or nipple; thirdly, by tatooing, as in the cases recorded by Josias and Maury, the pigments having been mixed with the saliva from a person affected with mucous patches of the mouth; fourthly, by unnatural connection, giving rise to chancre of the anus and perineum; fifthly, by linen, towels, pipes, spoons, toys, tumblers, pencils, bank-notes, and other articles; sixthly, by surgical instruments, sponges, and

dressings; seventhly, by chamber-pots and water-closets; and, lastly, by the fingers of the affected individual. In this manner a person may inoculate his own lips, nose, eyelids, or any abraded, raw, or open surface upon any portion of the body. In this way, too, accoucheurs sometimes inoculate their fingers in examining women laboring under chancre of the vulva, vagina, or uterus. Syphilis has been contracted by chewing the stumps of segars; and during the late war numerous cases occurred in which it was communicated by vaccinating soldiers with lymph from infected persons. In the valley of Rivalta, in Piedmont, in 1861, forty-six out of sixty-three children suffered almost simultaneously from this form of inoculation, several of them having died before the true nature of the disease was suspected. In these cases the real agent of contagion is the blood of persons in the secondary stage of the affection, which is mixed with the lymph; and the blood corpuscles of the menstrual discharge of syphilitic women, is declared by Dr. Hyde, of Chicago, to be not an unfrequent source of contagion.

The fact that the semen of a man laboring under constitutional syphilis is capable of communicating the disease, has long been familiar to practitioners. It is also a well ascertained fact that there are certain urethral discharges, occurring in persons affected with syphilis, which are of a contagious character, and therefore capable of imparting the disease to a healthy female, or to one who has never suffered from syphilis. Such fluids, mixing with the semen in its passage along the urethra, are supposed by Mr. Henry Lee, of London, to be a not unfrequent cause of hereditary syphilis.

SECT. II.—PRIMARY SYPHILIS.

Primary syphilis consists, as already stated, of chancre and bubo, that is, of the initial lesion, and of an induration of the lymphatic glands in anatomical relation with the former. The disease is not, as was formerly supposed, strictly local when it is limited to these phenomena, but it is an evidence that the system is already contaminated by the syphilitic virus.

1. CHANCRE.

If what is said under the head of chancroid be true, it follows, as a logical sequence, that there is only one truly syphilitic sore, the most appropriate name for which is chancre. The phrase, "initial lesion," introduced by the German writers, is also quite expressive, and is much in vogue in this and other countries. Hunter described a form of chancre which has long been known by his name, the characteristic feature of which is great hardness with an excavated condition of the resulting ulcer. This form of chancre mentioned with special emphasis by many of the earlier writers on venereal diseases, must have been much more common formerly than it is at present; for experience has shown that, while induration exists in almost every case of the disease, the form of sore here referred to is comparatively infrequent. Thus, of 170 cases tabulated by Bassereau, superficial erosions existed in 146, and circumscribed sores with abrupt edges, or sores falling under Hunter's distinction, only in 24.

Syphilis occurs, as a primary disease, under two varieties of form, the acquired and the inherited; the former, as the name implies, is the effect of direct contact in which infected tissue is brought in relation with sound tissue, whereas the latter is the result of the contamination of the ovum either in the act of copulation or at a variable period after that act. In either case, the cause of the disease is a peculiar virus, known as the syphilitic virus, the precise nature of which has never been satisfactorily unravelled either by chemical analysis or microscopical observation. All that is really known respecting it is that it is a zymotic virus, similar, in this respect, to the virus of measles, scarlatina, or variola, and capable of producing a constitutional impression which, as a rule, secures immunity to the system from future attacks. It differs, however, from the ordinary zymotic diseases in the fact that it passes through distinct stages of development, and that its germs may forever remain in the system, liable to be called at any time into activity, if, from any cause, the person experiences great impairment of his health. It is, moreover, transmissible from the parent to the child.

The site of chancre is very extensive, more so, indeed, than that of chancroid. In the male the parts most frequently involved are the head and prepuce of the penis. Of 476 cases of this disease observed at the Hopital du Midi in 1856, 314 occurred in these situations. The skin of the penis was affected in 60 cases, and various parts of this organ in 11 more; the meatus in 32 cases, the interior of the urethra in 17, the peno-scrotal angle in 11, the anus in 6, the lips in 12, and the tongue in 8; the nose, pituitary membrane,

eyelids, fingers and leg each in 1. I have repeatedly seen chancres on the fingers in medical men, and chancre of the lips is by no means uncommon in the women treated for venereal diseases at the Jefferson Medical College Hospital. In the female sex chancre is most frequently witnessed upon the labia and nymphæ, the entrance of the vagina, meatus, fourchette, and anus. In suckling women the nipple is occasionally inoculated by an infecting infant. The uterus rarely suffers from chancre.

The question, whether chancre has a period of incubation has been so often answered affirmatively that it would be idle to discuss it in a work on surgery. All zymotic diseases have a period of this kind, and syphilis forms no exception to the general law. In syphilis it averages from two to three weeks, but it often extends to a much later date, and as remotely even as fourteen weeks; on the other hand, in exceptional cases, the period is only ten days. It is not to be inferred from the word " incubation" as here used that the virus of syphilis lies perfectly latent in the inoculated part from the time of exposure to the appearance of the sore; on the contrary, it begins its zymotic operation within a very brief period, and rapidly penetrates the system, the entering wedges being the lymphatic vessels. This effect is always, other things being equal, produced more promptly when the infecting matter is brought into contact with an open, ulcerated, or abraded surface than when it is entangled in the orifice of a mucous crypt or sebaceous gland, in either of which it may lie literally in a state of latency for several days, if not several weeks.

Chancre, as already stated, appears under no exclusive form, but is susceptible of great variation, assuming at one time this feature and at another that. The superficial form is most common on the mucous membranes, especially in those situations which are free from friction and exposure to the air and other sources of irritation; it is generally of a rounded or oval shape; the base is slightly depressed, seldom excavated, smooth or even partially polished, and of a reddish, livid, or grayish color. Its size varies from that of a split pea to that of a five-cent piece. It is generally solitary, has no areola and, unless irritated, does not furnish any pus globules, but only a thin, serous secretion, small in quantity and destitute of autoinoculating properties. On the skin the ulcer is generally more depressed, and its edges more defined; it is also more liable to be covered with scabs, and to give rise to appearances closely simulating certain forms of secondary eruptions, as the pustular and ecthymatous. In both structures, the mucous and cutaneous, induration constitutes a conspicuous if not an invariable concomitant of the ulcer, as is well shown in fig. 78, from a hospital patient.

The number of chancres offers a remarkable contrast to that of chancroids; while the latter are generally multiple the former are most frequently solitary, certainly in three cases out of every four. Such, at all events, must be our conclusion if we may credit the

Fig. 78.

Indurated Chancre.

statistics of 1584 cases compiled by Fournier, Clerc, Hammond, and Le Fort, of which 465 only were multiple. Occasionally the number ranges from two, three, five, or even six, and in one remarkable instance, observed by Fournier, there were as many as nineteen.

Chancre, as might be supposed, is liable to certain modifications in its appearances, depending upon various causes, local and constitutional, individual peculiarity, and, no doubt, also upon the character of the poison itself; for there can be no question that it is much more virulent in some cases than in others. In the so-called Hunterian chancre, fig. 79, the ulcer is hollow as if it had been scooped out of the tissues, and incrusted with a layer of very firmly adherent fibrin, of a dirty-grayish color. The edges are hard, slightly elevated, and inclined somewhat slopingly from within outwards. The base is well defined and remarkably hard, feeling, if pressed between the thumb and finger, like a button of fibro-cartilage, or, to employ the comparison of Benjamin Bell, like a split pea set in the structures immediately around the chancre. This form of sore is, as already stated, most common on the skin, but is also sometimes met with on the head of the penis, the inner surface of the prepuce, the labia, uterus, and lips.

A diphtheritic condition is very common in chancres, and is especially liable to occur when there is, from any cause, overaction in the sore; the plastic matter which gives

rise to this appearance is usually deposited in a thin, firmly adherent layer, more or less moist, and of a dirty, grayish, or greenish color. The neighboring structures are more or less inflamed, and often highly sensitive, if not actually painful.

A chancre occasionally appears as a hard knot or tubercle, of an indolent character, free from pain, and indisposed to take on ulcerative action. The frenum and edges of the prepuce are its most common seats.

Fig. 79.

Hunterian Chancre.

A chancre never suppurates except when it is irritated by friction, exposure, want of cleanliness, or improper applications. When this is the case it pours out pus, in greater or less quantity, precisely as any ordinary sore, and the fluid thus furnished may, by admixture with the natural secretion of the chancre, become inoculable. It is a fact worthy of notice that chancre and chancroid may coexist, or be ingrafted, so to speak, the one upon the other. In such an event, one sore will be hard and the other soft, or, if the ulcers run together, one part will present this feature, and the other that. This form of chancre is probably of more frequent occurrence than it is generally supposed to be. Professor Sigmund, of Vienna, who has made it a special study, inoculated the pus of a chancroid upon the infiltrated tissues of a hard papule with an unbroken surface, and in less than two days an open sore was established, one part of which was soft, while the other, or deep portion, exhibited all the characteristic features of a Hunterian chancre, and was the seat of the true syphilitic virus.

The natural color of a chancre is reddish or grayish, but this is liable to be changed by overaction of the part, however induced. A muddy, darkish, or blackish appearance is by no means uncommon, especially in persons of dilapidated constitution or intemperate habits, and is always denotive of the existence of molecular gangrene. Phagedena or gangrene in mass, as it may be termed, is occasionally witnessed under similar circumstances, and may, if not speedily arrested, be productive of great havoc. Nevertheless, such occurrences are far less common in chancre than in chancroid; and the serpiginous ulcers, so often witnessed in chancroid in persons of deteriorated health, are rarely seen in similar conditions in chancre.

What is known as the *multiple herpetiform* chancre, originally described by Dubue, is a rare form of ulcer occasionally met with on the head and foreskin of the penis and on the labia and vulva, occurring in the form of superficial erosions, of a rounded shape, of a deep red or coppery hue, and originally hardly the size of a millet-seed, but liable to enlarge as they progress, and finally to coalesce or run into each other. They are very sensitive, bleed readily under rude contact, and generally, as their name denotes, exist in considerable numbers, as many as a dozen, fifteen, or even twenty, coexisting or forming in more or less rapid succession. From ordinary herpes with which they are liable to be confounded they are distinguished by their smooth and shining surface, by their slightly indurated base, by their persistency, which is seldom less than four or five weeks, by the absence of itching, and by the induration of the lymphatic glands of the groin.

Under the name of *infecting balano-posthitis* Mauriac has given an account of a rare form of chancre, which consists essentially in a thickened, reddened, and excoriated condition of the mucous membrane of the prepuce and head of the penis, attended with more or less induration, tumefaction, and cell-infiltration. The disease is characterized by its chronicity, and by more or less involvement of the neighboring lymphatic glands; circumstances which readily distinguish it from ordinary balano-posthitis.

Finally, there is what Lancereaux, Bumstead, and others have described as the *dry chancre*, an extremely rare form of the disease, in which the head of the penis is incrusted with patches, of a round or oval shape, of variable size, and of a whitish or grayish color, beneath which the superficial structures are more or less thickened, indurated, and filled with cells. Dr. P. A. Morrow has published the particulars of a rare case of chancre, in which the head of the penis was covered with a membranous hood; but in this instance the deposit was moist and glistening, and, although firmly attached, unaccompanied by hardness or ulceration. The disease pursued an indolent course, and was followed by secondary symptoms.

Induration forms a prominent feature in chancre, and hence is of great diagnostic value; indeed, it is the most characteristic sign of the disease. It is seldom observable before the eighth or tenth day from the exposure, and never, as a rule, attains its maximum development under a fortnight. Of 261 cases of chancre treated by Sigmund, the induration occurred on the ninth day in 71, on the tenth in 84, on the fourteenth in 76, on the seven-

teenth in 15, on the nineteenth in 12, and on the twenty-first in 3. In 438 cases reported by Le Fort, the average period was nineteen days; in 5 cases the induration was noticed between the second and fourth days, and in 60 between the fifth and eighth days. Diday, in 19 cases, found the mean duration to be fourteen days, while Chabalier, in 96 cases, was induced to place it at eighteen days. Similar testimony in regard to the tardy development of chancre has been furnished by Castelnau, Gibert, Rollet, Bumstead, Bellehomme, Martin, and many other syphilographers. The fact, indeed, is familiar to every experienced practitioner. In rare examples the period of its appearance has been known to exceed one month. Occasionally the induration precedes the ulceration; and it is not uncommon for it to persist long after the primary sore is healed; or it may disappear, and then recur, perhaps a second, third, or even a fourth time, with or without reopening of the old sore. In exceptional cases the induration constitutes the only evidence of the initial lesion of syphilis. Its approaches are usually very insidious, and unaccompanied by any of the evidences of ordinary inflammation. Its boundaries are always well defined, but its consistence is generally more or less influenced by the seat of the chancre, or the nature of the affected structures. Thus, on the skin, it always, as a rule, in the fully-developed chancre, imparts the sensation, if pressed between the thumb and finger, of a hard lump or piece of fibro-cartilage. This form of induration is especially conspicuous in the so-called Hunterian chancre, striking illustrations of which are so constantly met with in chancre of the lips, and, occasionally also, upon the head of the penis, as well as in other localities. In chancres, on the other hand, seated in the mucous membranes, and presenting themselves as superficial erosions, the induration is commonly of the parchment-like variety, the affected structures feeling as if they rested upon a layer of that substance. In exceptional cases, as rare as they are generally difficult of accurate discrimination, there is an entire absence of induration; or, in other words, the chancre is soft, and yet not any the less infecting.

The cause of the induration is the new growth of connective tissue, which surrounds the chancre evenly and completely, forming around it a distinct and well-defined wall, without any blending into the neighboring parts, differing thus from an ordinary inflammatory deposit which is always lost insensibly in the circumjacent structures.

The duration of chancre varies in different cases and under different circumstances, but, as a general rule, it is somewhat less than that of chancroid. If the person is in sound health at the time of the exposure, and guards himself well afterwards, he will be likely to fare much better than one in an opposite condition. How far the mercurial treatment, to be discussed by-and-by, may influence the duration of chancre is still an open question. As a rule, no patient is safe so long as the ulcer is not in a healthy granulating condition. It is now fully established that one attack of chancre effectually protects both the part and system against a second attack, the poison of syphilis thus resembling, in its habits, the poison of variola and similar diseases; chancroid, on the contrary, exercises no such influence, one attack affording no immunity against another. Artificial inoculation performed upon persons previously effected with syphilis produces no positive effects, conclusively showing that there is no susceptibility to future invasion.

Does a chancre ever leave any *cicatrice* or scar? This question is one of great interest both in a diagnostic, therapeutic, and juridical point of view, and should therefore always be carefully considered. In the more simple forms of the disease, in which there never is any appreciable loss of substance, the process of cicatrization effectually obliterates all traces of the chancre, save, perhaps, in the skin, in which there is occasionally a slightly bronze-colored hue; but it is far different when such a sore has been assailed by phagedenic, gangrenous, or sloughing action. Here, as there is always more or less destruction of tissue, a scar, more or less depressed, indelible, and a few shades lighter than the adjacent surface, is inevitable, and always, at least as a rule, easily detectable. No patient can be said to be entirely well so long as the cicatrice of such a sore remains hard: the induration is an evidence that some of the virus still lurks in the affected structures, where it may at any moment be fanned into activity.

The complications of chancre are inflammation, phagedena, and gangrene, but these affections are not so common as they are in chancroid, under which head they are fully described. The affections of the lymphatic glands and vessels will be considered in the succeeding section.

Diagnosis.—The subjoined table shows at a glance the typical differences between chancre and chancroid. The most reliable signs of the former are the period of incubation, induration of the associated lymphatic glands, and induration of the base of the sore.

CHANCRE.

1. A constitutional disease, dependent upon the inoculation of a peculiar poison the product of a chancre, a mucous patch, or of contaminated blood.
2. Generally seated on the genital organs, but may also occur on the lips, nipples, fingers, and other structures.
3. Has a distinct period of incubation, varying on an average from eleven to twenty-one days.

4. Begins as an excoriation, or induration, generally in the form of a papule, or a tubercle which, in time, undergoes ulceration.
5. Advances slowly and heals rather rapidly.
6. Is generally single; multiple, if at all, usually so from the start from primary inoculation.

7. Form; round, or oval, generally as a superficial erosion; flat or slightly elevated; rarely deep, or excavated.
8. The floor of the ulcer smooth, red, and of a livid, or copper color; often grayish, muddy, or slightly greenish, especially if incrusted with plasma.
9. Edges sloping, as if the sore had been scooped out; flat, and adherent.
10. Discharge scanty and serous, and autoinoculation either impossible or effected with great difficulty.
11. Induration almost invariable, especially in men; sometimes absent in women; cartilaginous or parchment-like in its feel; circumscribed, movable, indolent, and persistent.
12. Generally insensible; hence often overlooked.
13. Occurs seldom, if ever, more than once in the same individual.
14. Seldom invaded by phagedena or gangrene.

15. Induration of the lymphatic vessels, common, especially in those of the penis.

16. Neighboring lymphatic glands indurated, painless, and freely movable; suppuration uncommon, and pus never autoinoculable.

17. Difficult of eradication, but may be improved by mercury and other remedies.
18. Is peculiar to the human race; at least the results thus far obtained tend to this conclusion.

CHANCROID.

1. A purely local affection, due to the inoculation of a contagious matter, wholly different from that of chancre.
2. Most common on the genital organs, whence it may extend to the groins, perineum, and the anus, especially in women.
3. The action of the poison begins at once, the ulcer usually attaining its full development and specific character by the end of the third to the fifth day.
4. Appears originally as a pustule, sore, or ulcer, and retains the character of an open surface throughout.
5. Progresses rapidly but heals slowly.
6. Frequently multiple, if not from the start, soon rendered so by autoinoculation from diffusion of the secretion.
7. Irregularly rounded, oval, or fissured, the sores often running into each other, and accompanied by a tendency to burrow.
8. Dirty-yellowish white, grayish, or pale pink; ragged, or worm-eaten.

9. Edges abrupt or perpendicular; eroded, and often undermined.
10. Abundant, thick, purulent, and readily autoinoculable.

11. Always wanting, except when the sores have been irritated by caustic or other harsh applications.

12. Always more or less painful.

13. May occur an indefinite number of times.

14. Inflammation often runs high, and may then end in destructive action, especially in broken-down persons.
15. Very uncommon, but may attend when the sore has been unduly inflamed by local irritants or a bad state of the system.
16. Bubo exists in about one-third or one-fourth of the cases; disease always inflammatory, and tending to suppuration; the pus frequently autoinoculable.
17. More or less amenable to simple local and general remedies.
18. May, it is believed, be transmitted by inoculation to some of the lower animals.

Chancre of the Urethra.—Chancre occasionally attacks the urethra; probably much oftener than is generally supposed, although its relative frequency to chancre of the prepuce and head of the penis has not been satisfactorily determined. Of 171 cases of chancre in males observed at the Hôpital du Midi at Paris in 1856, 17 involved the urethra and 32 the meatus. The fact that chancre is liable to occur here was not known, even to the most enlightened syphilographers, until within a comparatively recent period, and it is, therefore, not surprising that many of them should have considered gonorrhœa as capable, in some cases, of giving rise to secondary symptoms. The sore being concealed in the urethra, the discharge which attended it was regarded as being exclusively the product of gonorrhœa, and the ignorance which existed upon the subject would probably never have been removed if it had not been for the practice of inoculation. The numerous experiments which have been performed upon the subject have proved, beyond the possibility of doubt or cavil, that gonorrhœa is a merely local affection, and that, whenever any constitutional syphilitic phenomena occur as the consequence of a urethral profluvium these phenomena are due, not to the effects of gonorrhœa, but to those of urethral chancre.

Chancre of the urethra is generally situated immediately behind the meatus, or in that

portion of the canal which corresponds with the glans ; I have, however, repeatedly met with it on the lips of the external orifice, and in a young gentleman, recently under my care, there was a well-marked indurated chancre at least two inches behind the anterior extremity of the tube. The disease occasionally, although very rarely, extends over nearly the whole of the urethra, as far back as the neck of the bladder.

The period of latency of chancre of the urethra is much longer than in the ordinary form of the disease, being seldom less than three and a half or four weeks. The reason of this would seem to be that the specific virus, entangled in some of the lacunæ of the canal, is incapable of exerting the same rapid influence as when it is brought in contact with an abraded surface upon the head of the penis. Moreover, it is extremely probable that only a very small quantity of the poison generally finds its way into the urethra, and that, consequently, it has great difficulty, not merely in effecting a secure lodgment, but in so multiplying itself as to enable it to produce ultimately an explosive effect upon the mucous and submucous tissues. The urine, passing along the tube soon after the intromission of the specific fluid, generally either washes it entirely away, or, combining with it, effectually neutralizes its active properties.

The discharge attendant upon chancre of the urethra is always much less copious than in ordinary gonorrhœa ; it is also more thin, and of a lighter color, unless the accompanying inflammation is unusually severe, when it may be both profuse and of a thick, bloody character, or thick and yellow with a greenish tinge. There is generally some degree of scalding in micturition, though hardly ever so much as in gonorrhœa, and the site of the chancre is nearly always indicated by a sense of hardness, or a kind of lump easily distinguished by the thumb and finger. When the disease affects the anterior extremity of the tube, it is not uncommon to find great induration of the whole head of the penis, with a red and phlogosed appearance of its mucous covering, and considerable tumefaction of the prepuce. Morbid erections are not only frequent, but often very painful and troublesome. The disease is usually chronic, rarely gives rise to fever, and is always followed by constitutional symptoms. Bubo is seldom so distinctly marked as in chancre of the penis. More or less contraction of the urethra, especially in neglected or protracted cases, is an invariable sequence.

The diagnosis of chancre of the urethra is often difficult. It is easy enough when the ulcer is situated at the lips of the meatus, or just behind the orifice, the mere separation of the edges of which will then be sufficient to bring it fully into view. When located farther back, its existence becomes a matter of doubt ; for, although the accompanying induration may be very distinct, yet as a similar condition may be present in gonorrhœa, or stricture, as a consequence of a deposit of lymph into the submucous connective tissue, no useful deduction can be drawn from it. The most valuable rational symptoms are, the unusual latency of the poison, or the extraordinary length of time which intervenes between the impure connection and the outbreak of the disease, the remarkable obstinacy of the attack, resisting, as it generally does, all the various methods of treatment commonly directed for the cure of gonorrhœa, the slight scalding in micturition, and, lastly, the frequent variation in the nature of the discharge, which is now scanty, thin, and serous, now profuse, thick, and yellow.

Chancre of the Fingers, Lips, Tongue, and Anus.—Chancre of a finger may be contracted by surgeons and accoucheurs in examining, dressing, or delivering diseased women, from the accidental inoculation with the syphilitic poison. It commonly begins as a little sore or vesicle at the side of the nail, from which it gradually extends until it eventually involves its entire structure, as well as the surrounding parts. The attack is attended with great pain, discoloration, and swelling of the finger, which soon becomes bulbous and distorted, very much as in the worst forms of onyxitis ; and the ulcer itself presents a foul phagedenic or sloughing aspect. Red lines frequently extend up the arm, the axillary lymphatic glands are enlarged either alone or conjointly with that at the elbow, as well as exquisitely tender, and the general health is seriously impaired ; often, indeed, totally wrecked.

A chancre sometimes forms upon the lips ; more frequently upon the lower than the upper, as a result either of the contact of chancrous matter or of inoculation with the secretion of a mucous tubercle, as in the act of kissing, smoking, drinking, or glass-blowing. The sore is solitary, more or less oval, and characterized by a remarkably indurated base, the part feeling like a mass of fibro-cartilage. The discharge is scanty and ichorous. The whole lip is stiff, painful, and everted. Lymphatic involvement of the chin and side of the jaw is an invariable sequence.

In chancre of the tongue, it is usually the tip of the organ that is affected. The sore is very hard and indolent, but possesses no distinctive features.

In chancre of the anus the sores, which may be solitary or multiple, may be seated just at the verge of the anus, or immediately above the sphincter muscle, and are distinguished by their hardness, their rosaceous color, and their slow and painless development. Defecation is exquisitely painful, the parts are excoriated and inflamed, the discharge is thin and fetid, and, if the morbid action be not speedily arrested, abscesses are liable to form, although they seldom open into the bowel. Buboes rarely follow.

Chancres are liable to form in other parts of the body, as the nose, cheeks, eyelids, scalp, trunk, and extremities, and it is remarkable that in all these situations the sores invariably belong to the indurated variety of the disease.

The diagnosis of chancre of the fingers, lips, tongue, anus, and other portions of the cutaneous, mucous, or muco-cutaneous surface must be deduced from the history of the case, and from a careful examination of the affected structures. It should be borne in mind that a chancre of the lip may be mistaken for an epithelioma; and no surgeon should ever be in haste to amputate a syphilitic finger, when the ulcer presents a foul or sloughy aspect, inasmuch as a judicious course of treatment may promptly cure the disease.

Is syphilis a curable disease? Does it ever disappear spontaneously, or eventually lose its hold upon the system, so that a patient may be said to be perfectly well? These are grave questions, and it is much to be regretted that we cannot, in the existing state of the science, return satisfactory answers. From all the light that at present exists upon the subject, I think it may fairly be assumed that, as a rule, when a man has once been syphilitic, he will always be syphilitic; in other words, that the germs of the disease remain forever in the system, liable, under adverse circumstances, to be at any time, however remote from the primary inoculation, fanned into activity, or, figuratively speaking, to rise, like a phœnix, from its ashes. That the virus is, in exceptional cases, as rare as they are difficult of detection, completely eliminated from the constitution, is unquestionable; at all events, such is the conclusion arrived at after a thorough study of the subject in all its phases by some of the ablest and most experienced syphilographers of the present day, men who are not easily led astray by speculation or conjecture. But, although syphilis is generally an ineradicable disease, it is consolatory to know that it is no longer endowed with the virulence which characterized it in former times, and that, under proper treatment and hygienic precautions, the disease may be kept indefinitely in a state of abeyance, without danger to the patient or to his offspring.

Can syphilis give rise to pulmonary phthisis and carcinoma? Here, again, are two important questions, for the solution of which facts are still wanting. I have, myself, long been satisfied that syphilis, in persons of depraved constitution, often acts as an exciting cause of tubercular disease of the lungs and other organs, but only in cases in which there is a well-marked or deeply ingrafted predisposition to that affection. When no such state of the constitution exists, I do not believe it possible for the poison ever to produce such an effect. As to carcinoma, there are at present no facts before the profession to warrant the assertion that syphilis, in any of its forms, is capable of engendering it.

Treatment.—Much stress was formerly laid upon what was called the abortive treatment of chancre, on the supposition not yet entirely abandoned, that, if the inoculated structures could be effectually destroyed before the end of the fifth or sixth day, or the supervention of induration, which forms so characteristic a feature of the disease, all danger of the entrance of the virus into the system could thereby be averted. This doctrine is, however, no longer tenable, for, as was previously stated, there is reason to believe that the virus begins to act the moment it is brought into contact with an abraded surface, or the interior of a mucous follicle, and that, consequently, it does not, except in very rare cases, have, as was so long conjectured, any period of latency, properly so termed, however short. If we assume that this supposition is true, and few syphilographers of the present day doubt or deny it, then all abortive measures must necessarily be futile. The opinion of Ricord upon this subject is positive, and emphatic. He has entirely abandoned the practice of cauterizing and excising chancres. He considers all such procedures perfectly useless, experience having shown that even before there is any appearance of a sore or tubercle, constitutional syphilis already exists. " If," says he, " the penis were amputated on the appearance of an infecting chancre, syphilis would none the less be produced." I have, myself, repeatedly destroyed incipient chancres with the knife, acids, or escharotics, and yet in no solitary instance which I can now recall was the operation successful in preventing the development of constitutional symptoms. When

a man applies for advice, with a suspicious looking sore or abrasion, within a few hours after impure connection, the surgeon should not hesitate to employ means for the destruction of its specific properties ; the treatment might, and probably would, fail ; but if properly conducted, it could do no harm, and would, certainly, for a time at least, calm the patient's mind, an object, frequently, of the greatest importance, especially if, as so often happens, he is very nervous or excitable. If, on the other hand, several days have elapsed, or induration already exists, all such interference will be perfectly useless so far as the development of constitutional symptoms is concerned. But, although this is undoubtedly true, the operation, if early and thoroughly performed, will materially modify and abridge the local disease, and for this reason, always deserves serious consideration. When the work is decided upon, it should be done effectually, by including, if possible, some of the surrounding healthy structures. The best, safest, and least painful operation is excision, but, as few patients will submit to this, the next best thing is some acid or alkali, as the acid nitrate of mercury, nitric acid, or Vienna paste, cautiously applied, otherwise serious mischief may result. Ricord was in the habit of using carbo-sulphuric paste ; but the pain arising from it is so excessive as to render its employment highly objectionable, not to mention its tendency to spread too widely over the sound tissues. Nitrate of silver, whether in substance or solution, possesses no value as a neutralizer of the syphilitic virus. The treatment after the use of any of these agents should be conducted upon strictly soothing and antiphlogistic principles, conjoined with perfect rest until the more severe symptoms have disappeared.

Assuming, what is undoubtedly true, that, when a patient has once been thoroughly inoculated, constitutional syphilis is inevitable, the question arises, what is best to be done to render the outbreak as harmless as possible ; or, in other words, to eliminate the specific virus in the shortest time, and in the most thorough manner, from the system? It has been seen that this poison is, among other properties, possessed of zymotic qualities, by reason of which it induces rapid cell-proliferation, the effect of which is to taint alike the solids and fluids, as is shown by the various affections that manifest themselves, first, in the dermoid and mucous tissues, and, subsequently, if the disease be not timeously arrested, in all parts of the body. To prevent the germination of this poison becomes, therefore, an object of the deepest possible interest. But is it possible to do this? Upon this subject, again, as, indeed, upon every other growing out of this disease, there exists more or less divergence of opinion ; but, I think, I state the matter fairly when I assert that much may be done in every case if taken in hand at an early period after inoculation, not in preventing the occurrence of secondary symptoms, but in retarding their access, in moderating their severity, and in abridging their duration. If this can be done, a great point will be gained, a point which it is the solemn duty of every practitioner to aim at. Medicine alone will not accomplish the object. To succeed, the patient must place himself unreservedly in the hands of his professional attendant. Every hygienic measure must be called into requisition ; the diet, if plethora be present, must be abridged, the bowels freely moved, and the mind and body kept at rest. These are points upon which it is impossible to lay too much stress, or without the due observance of which it will be possible to make any efficient progress. It is worse than useless to let the patient have his own way, or to permit him to follow his accustomed mode of living. The most reliable remedy, undoubtedly, for neutralizing the poison or eliminating it from the system, is mercury, in the form of calomel, administered thrice a day, in doses varying from the third to half a grain, a short time before eating. If the patient be plethoric, it will be well to combine with each dose of the medicine a few drops of aconite, or the tenth or twelfth of a grain of tartar emetic. The effect should, of course, be carefully watched, ptyalism being sedulously guarded against, and griping and purging prevented by the use of opium and an occasional dose of oil. To prove beneficial, the treatment should be steadily maintained for at least five or six weeks. Protiodide of mercury, blue mass, or gray powder may be used as substitutes for calomel, but, as a rule, the latter deserves the preference on account of its greater certainty and more manageable character.

If mercury is the only or principal remedy capable of neutralizing, eliminating, or destroying the syphilitic virus, how long should it be persisted in to insure this desirable result? Can this question be determined in any given case, or must every case be governed by its own laws? Manifestly, the practitioner must be guided here, as in the treatment of every other disease, by general principles ; but, as a rule, founded upon long experience, and acted upon by many of the most enlightened syphilographers, it may be assumed that the use of the remedy must be continued, more or less steadily, for at least from twelve to eighteen months. Some practitioners insist upon its exhibition for a much

longer period, as two or even three years, but if such a practice is at all justifiable, it can be so only in exceptional cases, cases in which the poison has taken more than an ordinarily firm hold of the the system. When the treatment is prolonged over such a length of time, there must always be great danger of inflicting serious injury upon the system, unless the mercury is administered in the smallest possible quantity compatible with its therapeutic effects, and with the greatest possible care and judgment.

Another excellent remedy, as an eliminator of the poison of syphilis in its incubative stage, is tartar emetic, in doses varying from the eighth to the tenth or twelfth of a grain, according to the tolerance of the stomach, thrice a day. It may be given by itself, or in union with aconite and sulphate of magnesia, in the form of the antimonial and saline mixture, with the positive assurance that it will rarely, if ever, disappoint expectation. It is certainly only less potent as a neutralizer or eliminator of the syphilitic virus than mercury.

As to the iodides in the treatment of primary syphilis, experience showed long ago that they possess no curative power, whether they are employed singly or in combination with other remedies, in small or in large doses. Practitioners, ignorant of the true action of these remedies, alone employ them in this stage of the disease, and hence much valuable time is often lost, time that should have been spent in the employment of other and more appropriate remedies.

Diday, who is regarded the world over as a great authority in syphilis, and who believes that, under certain circumstances, this disease tends to self-limitation, has published the results of forty-three cases treated by the non-mercurial plan, in twenty-six of which there was never any serious constitutional disturbance, the principal phenomena consisting of a mild form of fever, acne of the scalp, roseola, and mucous patches. Although these symptoms reappeared several times in most of the cases, each successive attack was milder than the preceding one, showing plainly, as he declares, that the disease was gradually dying out or losing its hold upon the system. No tertiary symptoms were developed, and all the patients gradually regained their health and vigor. The disease, according to this writer, will be most likely to be comparatively mild when to a protracted period of incubation there is superadded a gradual diminution of the engorged lymphatic glands, followed, perhaps, only by superficial blotches of the skin, or skin and mucous membranes, separated by long intervals. When the opposite conditions exist, the prognosis will necessarily be of a more grave character, inasmuch as they go to show that the disease is more deeply rooted, or more thoroughly inlaid in the general system, the blood and solids being alike contaminated by the operation of the virus. Although there may occasionally be cases of syphilis falling under the first of these divisions, no conscientious surgeon would be likely to adopt the expectant method of treatment in a matter which so seriously concerns the happiness of his patient. An error here would not only be a blunder, but might be followed by the most lamentable consequences.

The non-mercurial treatment of venereal diseases, formerly so much lauded, is completely divested of any value that was at one time attached to it, by the fact that the distinction which is now known to exist between chancroid and chancre had not been recognized; consequently both these affections were treated on the same principles. The British surgeons, during the Peninsular wars, furnished, as they supposed, the most irrefragable proof that primary syphilis could generally be effectually cured by ordinary antiphlogistic means; and similar testimony was supplied by the hospitals of Sweden, Hamburg, Strasbourg, and other continental cities of Europe. These reports, which at one time attracted universal attention, and were accepted by many practitioners with implicit confidence in their reliability, are now only fit for the waste basket.

How mercury acts in curing syphilis, whether as a neutralizer, or as an eliminator, is still a mooted question. In all probability it acts in both ways; certain it is that its presence has been detected again and again within a short time after its exhibition, in the urine, the perspiration, the saliva, and even in the alvine evacuations. Administered in small quantities, after the system has been properly prepared for its reception, it increases the number of red globules, while it decreases the number of white, and improves the general health by augmenting the appetite and the assimilative functions. In large doses, on the other hand, or when the system is brought under its prolonged influence, it produces directly opposite effects. These facts, which accord fully with the clinical observations of every enlightened practitioner, have been placed in the strongest possible light by the researches of Liégeois, Wilbouchewitch, and Dr. E. L. Keyes, whose excellent paper on the effects of small doses of mercury in modifying the number of red blood corpuscles in syphilis is replete with interest, and worthy of the attentive study.

During this mercurial treatment, *complications* must be looked for and properly met as

they arise. Thus, if the secretions be at fault, they must be promptly corrected; and until this be accomplished, it will be well to suspend the use of the specific remedy, as it could hardly fail to prove mischievous by acting as an irritant. If febrile disturbance arise, accompanied with a strong bounding pulse and a hot, dry skin, blood may be abstracted from the arm, or, what will usually answer quite well, recourse may be had to the neutral mixture, with the addition to each dose of two or three drops of the tincture of aconite. Opium in large doses, repeated more or less frequently, and conjoined with a suitable diet and perfect rest, will be absolutely necessary if phagedena or gangrene occurs. Ricord, in such an emergency, has unbounded faith in the utility of potassio-tartrate of iron, administered every five or six hours in syrup of orange peel, or some other suitable vehicle. The exhibition of mercury is at once suspended, and every effort made to tranquillize the part and system. If the patient is anemic or greatly debilitated, the use of tonics, as quinine and iron, milk punch, and other supporting measures will be imperatively demanded, perhaps at the very outset of the treatment.

In regard to the local treatment, little, if anything, needs to be added to what is said upon this subject under the head of chancroids. Local baths, either simple or medicated, are of paramount importance; they serve not only to cleanse and soothe the affected parts, but afford material aid in moderating inflammation. The frequency with which these baths are repeated, and the time during which they should be continued, must depend upon the amount of pain, swelling, discharge, and other circumstances. I am disposed to lay much stress upon them, for it is impossible to overestimate their value in a curative point of view. The best local application, in the intervals, is a moderately strong solution of acetate of lead, or lead and opium, applied upon soft lint, or, what is much better, cotton-wool, covered with oiled silk, and renewed as often as it becomes dry or soiled. An elm poultice, simple or medicated, is another most grateful application. Blood may be taken by leeches from the groins and inside of the thighs, if the local irritation is uncommonly severe, but these animals should not, for obvious reasons, be applied to the affected organ itself. Weak lotions of acid nitrate of mercury will be found to be the most suitable remedies for arresting phagedenic or gangrenous action; and occasionally nothing answers so well as weak solutions of subsulphate of iron, combining, as this article does, the properties at once of a detergent, an alterant, and a powerful antiseptic. Languid action demands the use of stimulants, of which, according to my experience, nitrate of silver is the very best. It may be applied in substance passed lightly over the affected surface once a day, or, what I generally prefer, in solution, as five, ten, or fifteen grains to the ounce of water. A tight, unretractable prepuce should never be incised, unless it acts as a tense cord imperilling the occurrence of gangrene, when it should be freely divided at all hazard, the raw surfaces being immediately cauterized with crystallized carbolic acid, nitrate of silver, or acid nitrate of mercury. Any œdema that may be present may be treated with dilute tincture of iodine; or, this failing, with a few small punctures, hermetically sealed with collodion as soon as thorough drainage has been effected. Morbid erections are controlled with anodynes, either in the form of suppositories or hypodermic injections. When the prepuce cannot be retracted, the syringe must be freely used; first, with simple warm water to wash away the secretions, and, immediately afterward, with weak solutions of lead, alum, chlorinated sodium, or some other suitable fluid, to promote the healing of the sores. When the foreskin is sufficiently soft and yielding, it should be kept constantly separated from the head of the penis, either with dry lint, which is often the very best application that can be made, especially when the first flush of inflammation is over, or lint wet with some mild lotion, as water containing two or three drops of acid nitrate of mercury to the ounce. Dry calomel is also sometimes beneficial; and now and then weak yellow wash answers a good purpose. Ointments are, as a rule, from their liability to become rancid and offensive, less kindly borne than fluids. Here, as in the case of chancroid, it is very important to watch closely the effects of our local remedies, making such changes from time to time as the exigencies of the case may demand. He who expects to treat successfully any case of chancre, of the least severity, with any one particular remedy, will generally find himself egregiously at fault. Finally, let it be borne in mind, as a solemn warning, that all harsh applications in the treatment of this affection, as in that of chancroid, will inevitably be productive of harm, provoking irritation, increasing pain, keeping up constitutional excitement, and protracting the cure.

The indolent form of chancre is always accompanied by great induration, which often continues long after the ulcer is completely cicatrized, and constitutes a variety of syphilis peculiarly dangerous on account of its liability to be followed by unusually severe and protracted constitutional symptoms. Indeed, no patient is safe so long as the part re-

mains in this condition. It is an incontestable evidence that the virus still lingers at the original seat of the infection, and that, like a smothered fire, it may spring up at any moment into a full blaze, reëxciting ulceration, and endangering the system. It is to this form of chancre that mercurialization is so emphatically applicable : no delay should be permitted, and it will generally be necessary to carry the treatment to the extent of slight ptyalism. When the desired effect is unusually tardy, the treatment may be aided by mercurial inunctions, from one to two drachms of the ointment being rubbed on the inside of the arms and thighs morning and evening ; or, what is better, a mercurial suppository may be inserted every eight, ten, or twelve hours, the effect of the remedy being carefully watched, lest overaction should be induced. The best local remedies are very dilute tincture of iodine, lead lotions, and inunctions of mild mercurial ointment.

The treatment of chancre of the urethra is conducted upon general antisyphilitic principles. The remedies which prove so serviceable in gonorrhœa are entirely inert here, except in so far as they may be instrumental in diluting the urine and depriving it of its acrimony. When within reach, gentle cauterization with nitrate of silver will be beneficial ; indeed, in obstinate cases, hardly any other direct application will be of much avail. In the intervals of the cauterization, or, in the more intractable forms of the disease, throughout the treatment, different kinds of injections must be used, especially weak lotions of sulphate of copper, tannic acid and opium, acetate of lead, bichloride of mercury, and iodide of iron. If the sore be seated near the meatus, the opposite surfaces should be kept apart with a tent medicated with dilute ointment of nitrate of mercury ; or a small bougie smeared with this substance may occasionally be introduced. If marked induration exists, early but gentle mercurialization must be employed. Chancres of the fingers, lips, tongue, anus, and other portions of the cutaneous, mucous, or muco-cutaneous surface must be treated on general principles. Nearly all of these affections will be materially benefited by a mild course of mercury.

SYPHILIZATION.

It was supposed at one time that syphilis could be effectually eradicated from the system, after the failure of all other means, by successive inoculations with the virus of this disease. To this treatment the term syphilization, first used by Dr. Auzias Turenne, was applied. As early as 1844, this physician, in attempting to transfer syphilis from man to the monkey, was struck with the fact that, when the operation was repeated a number of times, the tissues into which the matter was inserted were at length rendered completely insusceptible to its further influence. Believing that the treatment might be advantageously applied to the human subject, he instituted some experiments in this direction, but the results were not given to the profession until after the publication of the memoir of Dr. Sperino, of Turin, in 1851. In this memoir numerous experiments are detailed apparently confirmatory of those of Auzias Turenne. Subsequently the matter was very thoroughly investigated by the late Professor Boeck, of Christiania, the results of whose labors were widely disseminated through the medical press of Europe and America.

The value of the observations of these and other experimentalists is rendered completely nugatory when it is remembered that they were unicists, or believers in only one venereal poison. Hence, since it has been determined that chancre and chancroid are essentially distinct diseases, syphilization has lost all its scientific interest and practical value : it is an exploded myth which had its origin in misconception and the grossest absurdity. As stated in a former paragraph, it is now well ascertained that the inferior animals are insusceptible of contracting syphilis, and it is equally certain that chancroid is a strictly local affection, and therefore incapable of contaminating the system ; moreover, when a person has once had syphilis, he is, as a rule, as perfectly proof against future attacks as one who has had measles, scarlatina, or smallpox.

According to Boeck, whose name is indelibly associated with the history of this operation, syphilization is justifiable at all periods of life, but should only be resorted to after the development of secondary symptoms ; for, so long as the disease is in its primary stage, inoculation would be improper, as it cannot positively be determined beforehand whether the constitution will become tainted or not. The earlier the treatment is commenced the better, and the effect will always be the more prompt and decisive, when the patient has not been subjected to any previous mercurial course, as this renders the system more stubborn to its influence, and more prone to relapses.

In performing the operation, it is immaterial whether the virus is taken from a chancroid or an irritated chancre. The parts selected for the operation are the trunk and the inside of the thighs and arms. In a few days pustules form, the matter of which is in-

serted into the skin until no further effects result, when the virus of the primary sore
must again be employed, and the same course pursued as before, until the system is ren-
dered completely unimpressible. It will sometimes require, says Boeck, the use of a
new virus five or six times, before thorough constitutional immunity is secured. The
symptoms generally begin to abate in from four to six weeks, but it may take many months
or even an entire year before the disease is perfectly eradicated; the average period being
about 134 days. It will be found, upon every repetition of the inoculation, that the pus-
tules and ulcers become less and less, and, also, that they gradually lose their specific ap-
pearance and character.

Dr. Boeck furnished the statistics of 502 cases, treated in the hospital at Christiania, of
which 429 took no mercury. Of the latter, 384 were completely cured. In the remainder
the disease relapsed. He declares that the success in his private practice was still more
flattering.

One cannot but regret in reading the contributions of Dr. Boeck and his followers that
so much time was misspent and so much labor wasted in an investigation that has been
productive of so little, if, indeed, any good. The treatment to which they devoted so
many years of fruitless toil, was not only very tedious and painful to their patients, but
so exceedingly filthy and disgusting that, even if it had had truth on its side, it could never
have been extensively, much less generally, adopted. Men would have shrunk from such
an infliction. Besides several surgeons who pursued this treatment were not only severely
censured, but prosecuted and heavily mulcted. Long before the downfall of syphilization
as a practical matter, it was shown by Mr. Lee, of London, and Dr. Lindwurm, of Munich,
that the alleged beneficial effects of the operation were due, not to any specific influence of
the inoculation, but to the depurating effects of the resulting ulcers upon the system, the
continuous suppuration serving as a salutary drain. For much interesting and valuable
information on this and other subjects of syphilization, the reader is referred to an exhaust-
ive paper of Dr. Öwre in the London Medical Times and Gazette for 1868.

2. AFFECTIONS OF THE LYMPHATIC GLANDS AND VESSELS.

These affections consist mainly in induration of these structures, liable of course to be
modified during their progress by various inflammatory accidents. More or less indura-
tion of these bodies is present in almost every case of chancre. Ricord lays it down as a
pathological law that a chancre cannot exist without induration of the associated lym-
phatic glands; "induration," he says, "follows a chancre as a shadow follows a substance."
In this opinion most syphilographers of the present day fully concur, and yet it would be
wrong to assert that this law has not an occasional exception. Bumstead, who affirms
that he has never met with a chancre which was not attended by induration of the neigh-
boring lymphatic glands, regards it as a far more reliable symptom of a chancre than
induration of the base of the ulcer itself, inasmuch, he adds, as it is more constant and
persistent, and less likely to be counterfeited by extraneous influences. The frequency of
this condition of the lymphatic glands may be inferred from the statistics of some of the
French syphilographers. Thus Bassereau found it in 355 out of 380 cases of chancre,
the diagnosis of which was confirmed by the evolution of well-marked secondary symptoms.
Of 265 examples reported by Fournier the lymphatic glands were affected in 260. Rollet
collated 26 cases of artificial inoculation with the virus of syphilis performed upon persons
previously free from this disease, in only 20 of whom induration was detected. A number
of cases have been furnished of inoculation performed upon persons previously infected
with syphilis, in every one of whom the operation afforded none but negative results. It
may reasonably be supposed that gangrene or phagedena occurring very early in the pro-
gress of chancre might oppose the development of induration, although even this admits
of doubt; and it is also very probable that cases may arise in which the induration of the
lymphatic glands of the groin and other regions of the body is so thoroughly masked by
fatty matter or diseased structure as to render its detection utterly impossible.

The glands most liable to suffer from induration are, as a rule, those in closest prox-
imity with the seat of the original infection. Thus in chancre of the penis, urethra,
scrotum, vulva, vagina, uterus, perineum, anus, nates, inferior parts of the abdomen, and
the lower extremities, the glands of the groin are involved; chancre of the lips, tongue,
mouth, and chin, is followed by induration of the submaxillary glands; chancre of the
eyelids affects the anteauricular gland; and the axillary glands suffer in chancre of the
breast and of the upper extremity. In a case of chancre of the forefinger, Bumstead
found a well-marked induration in the web between it and the thumb; and Sigmund long

ago showed that the epitrochlear gland generally becomes enlarged and indurated when the disease breaks out on the hand or forearm.

The induration of the inguinal glands usually appears as early, or nearly as early as the induration of the base of the sore, that is, from the seventh to the eleventh day, when it may be said to have attained its maximum development. In exceptional cases, it occurs later, but rarely, if ever, earlier. It may affect both groins, as when the chancre is multiple or situated on the middle line of the genital organs ; but in ordinary cases it is limited to one side. Now and then, as in chancroid, the situation is reversed, owing to the peculiar arrangement of the lymphatic vessels, those of the right side, for instance, crossing over to the left, and conversely. In the groin, as in most other localities, where the glands occur in groups, nearly all are implicated in the induration, as in fig. 80, from Cullerier,

Fig. 80.

Syphilitic Buboes.

the smaller, varying in size from that of a bean to that of an olive, being closely agregated around a larger central one. The tumor thus formed is of a hard, dense, gristly consistence, of an irregularly rounded or oval shape, freely movable, devoid of pain and even tenderness, and without any attachment to the overlying integument, which always retains its normal color. The tumor, in fact, is an indolent, insensible mass, which retains its peculiar features from several weeks to several months, without, as a general rule, manifesting any tendency to suppuration, differing thus widely and characteristically from the course of a chancroidal bubo. Suppuration is not impossible, but in such an event the matter is small in quantity, of a thin, serous or sero-sanguinolent appearance, and insusceptible of autoinoculation. Of 968 cases of induration of the inguinal lymphatic glands, consequent upon chancre, recorded by Bassereau, Rollet, and Fournier, suppuration occurred in only 35. Hence, it may be laid down, as a rule, that, when an abscess forms in the groin, it is not the product of chancre, but of chancroid or struma, or of a non-specific inflammation. The diagnosis of this form of induration may usually be readily determined by the history of the case and by a careful examination of the affected region.

Induration of the lymphatic vessels is most frequently observed upon the penis, although it is not peculiar to this organ. It manifests itself in the form of dense, firm, whip-like cords, extending from the chancre towards the root of the penis, which, however, it seldom reaches. Sometimes a knotty or tuberculated appearance is present. The change which evidently depends upon interstitial deposits in the cavity of the affected vessels, is usually contemporaneous with the induration of the chancre and of the lymphatic glands, and is characterized by its persistency, freedom from pain, and indisposition to inflammation.

No treatment is generally necessary in these affections. Any tenderness that may arise during their progress will promptly yield to rest and to the application of tincture of iodine or of a few leeches, followed by a cooling laxative. Inflammatory irritation must be relieved by the ordinary antiphlogistic measures, and matter evacuated with the lancet. In general, the induration gradually subsides under the mercurial treatment, employed to cure the primary and constitutional disease, whether occurring in the lymphatic glands or vessels, of which it is simply one of the most constant and most persistent phenomena.

SECT. III.—SECONDARY SYPHILIS.

1. GENERAL CONSIDERATIONS.

The term secondary is employed to designate that group of morbid phenomena which manifest themselves after the occurrence of primary syphilis, the period of their evolution varying, on an average, from six to seven weeks from the first outbreak of the disease. The structures which are most liable to suffer are the cutaneous and mucous, and these may be attacked either simultaneously or consecutively, or one may suffer and the other escape, according to the condition in which they may be at the time of the contamination.

Secondary syphilis is always preceded by chancre. It often comes on before the initial lesion has disappeared ; a chancre, indeed, may, to use a figurative expression, be in full bloom, and continue to furnish an abundance of specific virus, and yet the constitutional disease have already made considerable, if not very serious, progress, the skin being perhaps covered with numerous eruptions, the throat inflamed or ulcerated, and the tongue affected with tubercles, thus showing thorough contamination both of the solids and fluids. Or, the chancre may be cicatrized, but remain hard and tender, more or less of the specific poison lurking in the affected tissues, ready to ferment and break out anew from the most trivial causes. Or, the original sore may have got entirely well, but the bubo be still active, either as an indurated swelling, or as an ulcer with more or less discharge. Or, lastly, and as is, perhaps, most commonly the case, the secondary complaint does not appear until some time after the primary has completely vanished, the patient having, perhaps, in the meanwhile, imagined himself perfectly well.

It is generally impossible to determine, in advance, what effect a chancre may exert upon the system ; or, in other words, whether it will be likely to lead to mild or severe constitutional contamination. We are, however, warranted in assuming that a mild attack will follow a long incubation and a superficial chancre, and that the symptoms will be severe when the incubation is short and the initial lesion is deeply ulcerated. If the patient be stout and robust, and, in every respect, well-conditioned, both as concerns his fluids and solids, at the time of the inoculation, the poison will be much less likely to do great harm than if he be feeble and exhausted by disease, or be laboring under the strumous or scorbutic cachexia.

Secondary syphilis is, under certain circumstances, an inoculable disease. It has been shown, for example, that matter taken from a mucous tubercle, a condylomatous excrescence, a pustular eruption, or a superficial ulcer of the mucous membrane, and, in fact, even the blood will, if carefully inserted into the skin of the arm or thigh, produce a chancre essentially similar to a primary one. The period of incubation, however, is much longer than ordinary, ranging, on an average, from twenty to thirty days, and the resulting ulcer, which is always indurated, is invariably followed by indolent enlargement of the neighboring lymphatic glands.

A remarkable feature of this secondary matter is that it will not generate a chancre in the person furnishing it, or even in another infected individual. To be capable of receiving the disease the subject must be free from all syphilitic taint.

That the blood of a person affected with constitutional syphilis is inoculable is clearly established by the fact that the disease has been repeatedly propagated from an infected to a sound person by vaccination, through the agency, not of the vaccine matter, but of the blood ; for Viennois has ascertained that there is not the slightest danger of infection when care is taken to keep the lancet free from this fluid in performing the operation, or when the operation is done with vaccine matter destitute of blood.

Numerous cases of this form of infection occurred during our late war ; and the outgrowth of the disease, vaccinio-syphilitic inoculation, has been made the subject of an elaborate and exhaustive essay by Professor Jones, of New Orleans. The sad effects of this mode of propagating syphilis are well illustrated in the cases that occurred at Rivalta in Piedmont, where an infant that had been vaccinated with infected matter communicated this malady to his mother and to forty-six children. One of the children thus contaminated imparted the contagion to his wet-nurse and to seven children. The fact that a tooth transplanted from the mouth of an infected person into that of a healthy one is capable of communicating syphilis was established long ago by the observations of John Hunter and other practitioners. Even the precaution of rubbing the surface of the tooth previously to its insertion did not always prevent contamination. The infecting character of the mucous tubercle of the tongue and lip is universally admitted. Indeed, not to

carry these illustrations any further, there is every reason to believe that many of the natural and abnormal secretions of every organ, tissue, or structure affected with syphilis are capable of propagating the disease, although it may be difficult to establish the fact by artificial inoculation. From some experiments performed by Mireur it appears that the semen of a person affected with chancre and secondary symptoms is not inoculable. In four persons thus treated no specific disease followed.

In 1877 a large number of cases of syphilis occurred in this city and at Reading from tattooing the arms on different persons, the operator, who was affected with mucous tubercles of the tongue, using his saliva for mixing his materials. An account of these cases from the pen of the late Dr. F. F. Maury and Dr. Dulles, will be found in the American Journal of the Medical Sciences for January, 1878.

Secondary syphilis is not only inoculable, but also transmissible from the parent to the offspring, the result declaring itself in a great variety of affections, more or less destructive to the new being, sometimes before, at other times not until after, birth. The very stream of life is thus poisoned, so that all those who are affected by it are destined to suffer from its effects, this being at least one of the ways in which "God visits the iniquity of the fathers on their children down to the third and fourth generation." The fact that the disease is transmissible shows that the whole system of the individual is impregnated with the specific poison, every globule of blood and every particle of solid matter being impressed by it. It is this pervasive, universal influence that has led to the opinion, now very general among syphilographers and practitioners, that constitutional syphilis is seldom, if ever, completely eradicable. Once implanted in the system, its germ is probably indestructible.

Secondary syphilis is usually ushered in by well-marked constitutional phenomena. From eight to fifteen days before there is any evident disease, the patient feels uncomfortable and unwell; he is irritable, gloomy, desponding, and unable to apply himself to business; his countenance has a dull, muddy aspect; his hair is dry and rough; his limbs and joints are sore and stiff; his appetite is impaired; the bowels are costive, or alternatively costive and relaxed; the urine is scanty and high-colored; exercise soon fatigues; headache is often present; and the sleep, disturbed by frequent dreams, is unrefreshing. Gradually, after the lapse of a few days, or, it may be, suddenly, he is seized with chilly sensations, or actual rigors, followed by high fever, or by fever and profuse sweats. When the disease is fully established, an increase of temperature of several degrees is often noticeable, especially in the afternoon and evening; and cases occur, although rarely, in which the fever assumes an indistinct periodical type. The attack, constituting what is called syphilitic fever, is manifestly an effort of the system to eliminate the specific poison, and the tissues upon which it usually expends itself are, as was previously stated, the cutaneous and mucous, together with the posterior cervical glands, the morbid phenomena of the former exhibiting themselves in various eruptions, and of the latter in ulcers of the throat and in mucous tubercles of the tongue and mouth. The iris also frequently suffers from secondary involvement. The blood is always more or less affected. As a rule, syphilis diminishes the number of red corpuscles below the normal standard, while the white are, in very severe forms of the malady, greatly increased.

2. AFFECTIONS OF THE SKIN.

The syphilitic affections of the skin, the syphilides, as they have been termed by Alibert, and the syphilodermata of more recent authors, occur under at least six varieties of form, the exanthematous, scaly, vesicular, papular, pustular, and tubercular. Of these, however, the last three, from their severity and late appearance, may be regarded as appertaining rather to the tertiary order of phenomena than to the secondary. Of the other three, two are not unfrequently coincident with the primary disease, although, in general, they do not come on until some time afterwards. To these syphilides may be added certain pigmentary changes originally described by Hardy, and more recently by Fournier, Pillon, Drysdale, Fox, Atkinson, and others. The syphilitic eruptions nearly always pursue a chronic course, are more or less circular in their form, and usually exhibit a characteristic copper color, especially in their earlier stages; for, after they have existed for some time, they are very apt to assume a grayish, muddy, or bronze appearance, owing to some modification in the pigmentary matter of the skin. Although occurring upon all parts of the cutaneous surface, they are usually most conspicuous upon the forehead, nose, cheek, back, and shoulder, together with the inside of the arm and thigh, and

are attended or followed by thin, grayish scales, hard, thick, greenish scabs, narrow, superficial cracks, or well defined ulcers.

Syphilitic cutaneous diseases are generally easily distinguished from ordinary skin diseases by, first, the history of the case, especially the presence or absence of chancre, or chancre and bubo; secondly, by the concurrence of lesions of the cutaneous and mucous textures; thirdly, by the pinkish-red, yellow-brownish, or faint copper color of the affected surface, dissipated by pressure in their earlier stages, but gradually shading off into a darker permanent hue; fourthly, by the total absence of itching, or of itching in a much milder and more evanescent form than in common skin affections; fifthly, by their tendency, at least in many cases, especially when they appear as papular and erythematous rashes, to assume a circular, rounded, or ring-like form; sixthly, by their polymorphism; and, lastly, by the fact that syphilitic eruptions are often found in regions of the body in which ordinary cutaneous diseases rarely, if ever, occur. Stress has been laid by certain authors upon the odors arising during the progress of some of the syphilides, especially the ulcerating; but, although the smell may occasionally be offensive, especially if cleanliness be neglected, it is never characteristic. All these affections are, as is now well known, liable to be modified in their evolution, course, and termination by various intercurrent acute diseases, as gout, rheumatism, pneumonia, and pleurisy; and also by the use of mercury and other remedies given for the relief of the primary maladies.

1. In the *exanthematous* form, the spots are of a reddish, pinkish, or pale copper color, circular in shape, and from the size of a dime to that of a twenty-five cent piece, the intervening surface being of a muddy, dusky aspect. Although they sometimes cover nearly the whole body, they are generally most prominent on the trunk and extremities; they are rarely confluent, do not disappear under pressure, and usually pass off with a slight desquamation of the cuticle. There is a variety of this eruption in which the spots are much smaller, more irregular in shape, and of a brighter red, the color resembling that of a new copper coin. From this circumstance, and from the eruption being often somewhat confluent, like measles, it is generally known by the name of roseola. In neither of these forms is there any actual elevation of the skin.

The syphilitic exanthem may be looked for in from six to twelve weeks after the appearance of the initial lesion. It often comes on before the disappearance of the primary disease, sometimes suddenly, and without any decided premonitory symptoms; at other times gradually, and with considerable pyrexial disturbance. As the eruption fades it loses its reddish tint, and assumes a dingy, dirty, dusky, or grayish aspect. Its duration varies from ten days to six weeks. Its gradual disappearance, and its coincidence with chancre, bubo, cervical adenitis, and other marks of syphilis, either primary or secondary, together with the absence of local distress, as itching and smarting, readily distinguish it from measles and other cutaneous affections. Syphilitic fever is absent in at least one-fourth to one-third of the cases in this form of the disease. On the other hand, there are few cases in which there is not marked enlargement of the lymphatic glands in different parts of the body, especially of those of the posterior cervical region.

2. The *scaly* variety of syphilis, or psoriasis, generally appears without any febrile disturbance, from two to six months after the primary disease; it is always remarkably chronic, lasting frequently for months together, and is commonly associated with ulceration of the throat and palate, iritis, and affections of the bones and joints; forming, in this event, a kind of connecting link between the secondary and tertiary stages of the constitutional infection.

The eruption, as the name implies, manifests itself in distinct scales, or thick, hardened portions of epidermis, of a dull, opaque, grayish appearance, resting upon a copper-colored base. It generally appears in separate patches, which, although liable to occur on all parts of the cutaneous surface, are most common on the forehead, scalp, face, forearms, palm of the hand, and sole of the foot, in the latter of which they often acquire a remarkable thickness. Each individual spot is from three to six lines in diameter, of a rounded shape, ordinarily isolated, rough, and somewhat elevated beyond the adjoining level. The scale is hard, whitish or grayish, and slightly adherent; the skin underneath has a tendency to ulcerate, or to form cracks and fissures, and when, by this means, its integrity is destroyed, the affected surface becomes covered with a thick, dry, brownish crust. When the part has cicatrized, a whitish spot, somewhat depressed at the centre, marks the original site of the disease.

3. The *vesicular* variety of syphilitic disease is very uncommon; it is, in fact, by far the rarest of all the syphilides. It usually begins coincidently with the latter stages of the primary sore, or soon afterwards, in minute, circumscribed pimples, scattered over

different parts of the body, to which soon succeed small vesicles, occupied by a transparent, serous fluid, and surrounded by a reddish, copper-colored areola. From the fact that many of these are traversed by a hair, it is not improbable that they have their origin in the hair follicles. Their progress is slow, and their contents are either absorbed, or transformed into thin scales, or scabs, which, falling off at different intervals, leave the skin of a dingy, yellowish hue, with small, depressed, temporary cicatrices. The vesicles, which may be small and pointed, large and globular, isolated or grouped, are occasionally so numerous as to cover nearly the whole surface of the body. In general, they are most common on the neck, chest, and extremities, especially the superior, their occurrence on the face and head being very infrequent. They usually coincide with syphilitic disease of the throat and nomadic pains in the bones and joints; a circumstance which, together with their copper-colored base, readily distinguishes them from ordinary vesicles.

4. Syphilitic *pustules* are circumscribed elevations of the skin, occupied by pus, or sero-purulent matter, and possessing a strong tendency to ulcerate. Although they occasionally coexist with the primary disease, they seldom appear until a long time after, and, therefore, generally appertain to the third order of symptoms, their presence being always denotive of profound constitutional contamination. Their size ranges from a pea to that of a small hazel-nut. In their shape they are conical, oval, pyriform, rounded, or flattened, with a minute central depression; and there are few instances in which these different varieties do not coexist. Their number is often immense, hundreds being scattered over a small extent of surface; and, as they form successively, they may be seen and studied in every stage of their development. Each pustule reposes upon a hard, copper-colored base, and occupies the deep layer of the dermis around the hair and sebaceous follicles.

After remaining for a short time, the contents of the pustule escape, concrete, and form hard, thick scabs, of a dark brownish, or olive-brown color, pretty firmly adherent, and sometimes circularly furrowed. In the more simple cases, the scabs soon fall off, leaving merely a chronic induration, a livid, dusky, or grayish stain, or a small cicatrice; but, in the more severe, deep, circular, characteristic ulcers are exposed, with a foul, grayish bottom, and a hard, purple, and well-defined margin. In cases of the latter description, the scabs are frequently renewed, and are finally succeeded by round, indelible scars.

The pustular syphilide comprises acne, impetigo, and superficial ecthyma, and the pustules themselves may occur in groups, or be disposed separately, without any tendency, as is sometimes the case with the other, to become confluent. The matter of these pustules is capable of producing chancre by inoculation.

The pustular form of syphilis is not unfrequently associated with the tubercular and papular, but rarely with the roseolar and squamous. Severe constitutional disturbance is generally present, and, indeed, the suffering may be so great as to destroy life, the health being gradually undermined by the excessive pain and irritation of the eruption and its sequelæ.

5. *Papular* syphilis, or lichen, is characterized by the occurrence of small, hard, solid elevations, containing no fluid, and terminating nearly always in desquamation, seldom in ulceration, or in the formation of scabs. There are two varieties of the affection, one of which is acute and primary, the other chronic and secondary.

In the first variety, the eruption appears simultaneously on different regions of the body, and is completed in about forty-eight hours from the time of its invasion. The papules are extremely small, disjointed, or grouped, of a red copper color, and of a slightly conical shape, being surrounded, here and there, by violet areolæ, which are often confluent, and give the surface a characteristic tinge. Ulceration rarely attacks these papules; they soon disappear, and are followed by a furfuraceous desquamation of the cuticle.

In the other variety, the eruption is developed in a slow, successive manner, being announced by small yellow spots, which are particularly numerous on the forehead, scalp, and extremities. The papules are of a light copper color, larger than the preceding, flat, of the size of small beans, grouped, and devoid of an areola. In time, the summit of each elevation is covered with a dry, grayish pellicle, which is regenerated as fast as it desquamates until the disease finally entirely subsides. Meanwhile, the skin between the agglomerated papules undergoes important changes: it assumes a dingy yellowish color, has a dry, shrivelled aspect, and is the seat of a constant exfoliation of the cuticle.

The papular eruption is often complicated with other syphilitic affections, as inflammation and ulceration of the throat, iritis, and nocturnal pains in the larger joints.

Occasionally it coexists with an imperfectly healed chancre or bubo, or with the scaly, pustular, or tubercular form of the disease. Iritis, in particular, is an exceedingly common accompaniment.

6. Of the *tubercular* form of syphilis, the most formidable of all, there are two varieties, in the milder of which the eruption consists of small, red, copper-colored eminences, varying, ordinarily, in size between that of a mustard seed and a pea. Of a rounded, flattened, or conoidal shape, they are either isolated, assembled in groups, or arranged in more or less perfect circles; they are smooth and polished, cause little or no pain, and soon become covered with a dry, scaly crust, which is generally reproduced as fast as it falls off.

In the more aggravated form, the tubercles are inordinately large, of a deep violet hue, and encircled each by a well-marked, copper-colored areola. After continuing thus for some time, varying from a few weeks, to several months, they inflame, suppurate, and are finally replaced by deep, foul, painful, irregular ulcers, reposing upon a hard, purple base. The thick scab which usually covers these erosions is repeatedly renewed, showing, whenever it is detached, an extension of the ravages of the sore. When the tubercles are numerous, the ulcers, running together, often acquire a frightful size, and, on healing, leave white, disfiguring cicatrices.

Pigmentary changes of the skin are most frequent on the side of the neck, but no region is entirely exempt from them. Fournier met with them in the former situation in twenty-nine out of thirty cases. The color is usually more or less brownish, or dirty, milk-like, unaccompanied by any elevation or depression of the affected surfaces, coming on gradually in patches from the size of a split pea to that of a twenty-five cent piece, circular, ovoidal, or more or less irregular in shape, discrete or confluent, generally supervening late in the disease, pursuing essentially a chronic course, uninfluenced by antisyphilitic treatment, and finally disappearing, after months or even years, without any appreciable alteration in the skin. In some cases the spots have a festooned appearance, and Dr. Fox, of New York, has given a drawing in which the discoloration presented itself in the form of a distinct ring with a dark central speck. The lesion, which is most common in women of a light complexion, is liable to be confounded with leucoderma, chloasma, and several other affections of the skin, from which it may, however, in general be easily distinguished by its deeper hue, its situation, and by the history of the case.

Syphilitic *ulcers* of the skin are characterized by their rounded shape and excavated appearance, the bottom having a foul, grayish aspect, while the edges are red, ragged, and inflamed. Their tendency is to spread and undermine the surface, several not unfrequently running into each other. The discharge is thin, sanious, or ichorous, fetid, and more or less profuse and irritating. These ulcers usually have a copper-colored base, and they are nearly always sequelæ of pustules, or tubercles. They occasionally exist in great numbers. The scars left by these ulcers are permanent, of a whitish color, and extremely liable to break out into open sores on the application of the slightest irritant.

Treatment.— The treatment of secondary cutaneous syphilis may be divided into common and specific, the first being of a general antiphlogistic character, while the second has for its object the neutralization or destruction of the virus upon the action of which the affection more particularly depends, and which, so long as it continues, exposes the system constantly to new outbreaks of the disease. In most cases it will be found to be advantageous to begin the treatment with antiphlogistic remedies; for, although they may not always, or perhaps even very generally, eradicate the poison, the salutary impression which they make upon the system, by ridding it of its impurities, and restoring the secretions, greatly paves the way for the more prompt and efficient operation of any specific measures that may afterwards be deemed advisable. A disregard of this rule is probably one of the chief reasons why the mercurial treatment of syphilis is so often followed by severe tertiary symptoms, the system not being properly prepared, by a course of diet, baths, purgatives, and other remedies, for the reception and beneficial action of the mineral.

Syphilitic fever should be combated upon the same general principles as any other sympathetic fever. If the symptoms run high, as indicated by the state of the pulse and skin, and the patient is young and plethoric, blood may advantageously be taken from the arm, followed by saline, and antimonial preparations, the bowels having previously been opened by a brisk cathartic. The action of the medicines should be promoted with tepid drinks, and, if there be much pain and aching in the back and limbs, a Dover's powder, or an anodyne and diaphoretic draught will be beneficial. The duration of the fever is usually very short, the disease often yielding to very simple measures.

When eruptions appear upon the skin, the most efficient treatment, according to my experience, is the *antimonial*, or antimonial and saline. The quantity of tartar emetic given at each dose must vary from the fourth to the eighth of a grain, repeated every three, four, or five hours, with the precaution of avoiding decided nausea, which is hardly ever desired. The object simply is to produce a sedative and alterant effect. It may be administered by itself, as in the milder forms of secondary cutaneous affections, or be variously combined with other articles, as sulphate of magnesium when there is constipation, aconite when there is much arterial excitement, or morphia when an anodyne and diaphoretic action is indicated. The salutary operation of the medicine will be greatly promoted by the daily use of the tepid bath, by diluent drinks, and by a strict observance of the antiphlogistic regimen.

How tartrate of antimony and potassium operates in producing its salutary effects in secondary syphilis of the skin has not been determined. It is not improbable that it may, as mercury is supposed to do, neutralize the poison of the disease by divesting it of its zymotic qualities; or it may act simply as an eliminator, by furnishing an outlet for the poison through the various emunctories, upon all of which this medicine is known to exert more or less influence.

Tartarized antimony is particularly worthy of confidence in the treatment of secondary syphilis of the skin, but it may also be advantageously exhibited in the various affections of the mucous membranes, although its effects here are generally less apparent. The remedy, however, is not infallible, and hence, when the disease is unusually rebellious, it should be replaced by mercury, given in the same manner, and with the same restrictions as in the primary form of the disease. Without being disposed, then, to discard mercury altogether, I am satisfied, from ample experience, that its use may very properly be limited to an exceedingly narrow circle of cases of secondary syphilis, and that, whenever it is rendered necessary, its action will be greatly promoted by the previous employment of tartar emetic. Calomel is, according to my experience, the best form in which it can be exhibited; the dose should vary from the fourth to half a grain, repeated twice or thrice in the twenty-four hours, properly guarded with opium, and carefully watched. Bichloride may be used when the system has been seriously damaged by intemperance and other debilitating influences.

With respect to the topical treatment, in the event of ulceration and discharge, cleanliness is of paramount importance, and is best effected by frequent ablutions with simple water or slightly medicated fluids, care being taken that they do not fret or irritate the skin. Cataplasms and warm-water dressings are among the more soothing local remedies. Various lotions are of service, as weak yellow-wash, and solutions of nitrate of silver, sulphate of copper, tannic acid, and glycerine. When the ulcers are obstinate, mercurial fumigations may be advantageously used. Ecthymatous pustules should be opened, and, after their contents are discharged, the cavity should be gently stimulated with acid nitrate of mercury or solid nitrate of silver. When a papular eruption is seated upon exposed parts, as the face and hands, its disappearance may be hastened by the local application of a weak ointment of ammoniated mercury, or the five-per-cent. oleate of mercury.

3. ALOPECIA.

During the progress of syphilis the hair of the scalp occasionally falls off, generally within the first six, eight, or ten weeks from the appearance of the primary sore, with which, consequently, it is not unfrequently coincident. The affection, which is known as alopecia, usually occurs in circular disks, of variable size, and of a well-marked copper color. It is commonly partial, showing itself in distinct patches, of which several may exist simultaneously, or as fast as one gets well another may succeed, and thus the malady may proceed until it has travelled over the greater portion of the scalp; or, instead of this, nearly all the bulbs may suffer at once, and the hair drop off in great numbers, leaving the head ultimately nearly completely bare. When the system is saturated with the specific virus, not only the hair of the scalp, but also the beard, the eyebrows, and the hair of the rest of the body may disappear. Two well-marked cases of this universal alopecia, both in young men who had suffered from indurated chancre upon the head of the penis, have fallen under my observation. In one the desquamation was associated with roseola and sore throat, and was never followed by a reproduction of hair anywhere; the patient, after having lingered for several years under the exhausting effects of rupia and nodes, died in a state of marasmus. In the second case, the alopecia

was succeeded by syphilitic sarcocele, and the hair was eventually regenerated upon the scalp, although it remained always stunted, and was remarkably coarse, stiff, and sparse.

The first sign of baldness is usually a loss of the soft and glossy state of the hair, which becomes dry, stiff, and brittle, breaking off very readily under the use of the comb. After a little while it is observed to fall off in great abundance; and the scalp is not only remarkably harsh and scurfy, but covered with muddy, dingy, or dusky, copper-colored blotches, generally of a circular shape, and apparently, although not in reality, somewhat elevated above the adjoining surface. Fever occasionally accompanies the affection; and pains in the bones and joints, seemingly of a rheumatic nature, ordinarily characterize the progress of the case. Regeneration of the hair, partial or complete, may generally be expected, even under apparently the most adverse circumstances.

Baldness, as an effect of syphilis, is a grave occurrence, and should, if possible, be promptly arrested. The first thing to be done is to cut off the hair, not closely, but sufficiently to admit of the requisite attention to cleanliness and medication. Shaving of the scalp is seldom necessary. The treatment, directed more especially to the relief of the diseased hair bulbs, must be essentially of a stimulating character, as the object is to impart tone and vigor to the whole of the affected surface. In the more simple cases mild lotions of alcohol and spirit of hartshorn, eau de Cologne and compound spirit of lavender, or alcohol, glycerine, and tincture of cantharides, either in equal, or in different proportions, may be advantageously used. Another excellent wash is a solution of tannic acid and sulphate of copper in equal parts of bay-rum and water, six grains of the former, and half a grain of the latter being added to the ounce of fluid. The application should be made twice in the twenty-four hours, the friction being performed with the hand and fingers, and steadily continued until there is a glow upon the surface. The scalp should be washed every morning with warm water and Castile soap, and well combed immediately after to promote cleanliness and the dislodgment of dandriff.

If soreness of the scalp exist, or if there be eruptions, papules, tubercles, or numerous dry and adherent scales, the most eligible application is a pomade made of ointment of nitrate of mercury, diluted with from seven to ten parts of simple cerate, mixed with a few drops of oil of jasmine and a little Cologne water, and thoroughly rubbed into the roots of the hair night and morning. Along with these means special attention should be paid to the state of the system, and, if the case threaten to be obstinate, or if the alopecia coexist with an indurated, indolent, or badly-healed chancre the patient should be brought as promptly as possible under the gentle influence of mercury.

4. LYMPHATIC ADENITIS.

The posterior cervical glands generally suffer at an early period of the constitutional involvement, becoming enlarged and somewhat tender, although never very painful, and rolling, when pressed with the finger, like so many little elastic balls under the integument. The swelling is generally most conspicuous in the glands along the upper two-thirds of the posterior border of the sterno-cleido-mastoid muscle, and along the root of the hairy scalp, extending frequently as far outwards as the mastoid process on each side. It is essentially of a chronic nature, often lingering for many weeks, and never terminating in suppuration. Diagnostically considered, this species of adenitis, from the constancy of its presence, is of great value, but from the want of practical tact to detect it, it is extremely liable to be overlooked. The number of glands involved seldom exceeds two or three, and in many cases the disease is apparently limited to a single one. Its occurrence is most common in young subjects, and it occasionally manifests itself at so late a period of the disease that it may then be considered as belonging to the tertiary rather than to the secondary order of symptoms.

In syphilis of the lips, tongue, chin, throat, palate, and tonsils, there is not unfrequently an enlarged and engorged condition of the glands at the base and angle of the jaw; and a similar affection of the gland of the arm immediately above the internal condyle of the humerus, between the biceps and triceps muscles is occasionally met with. Marked disease of the axillary glands, as an effect of constitutional syphilis, is very uncommon.

Syphilitic adenitis generally disappears under the treatment directed for the relief of other secondary affections. The enlarged glands may be rubbed twice a day with mild mercurial ointment or ammoniated liniment, or painted with dilute tincture of iodine. If much induration exist, the most eligible remedy will be gentle mercurial inunction.

5. AFFECTIONS OF THE MUCOUS MEMBRANES.

Secondary syphilis of the mucous membranes generally declares itself within a short time after the cure of the primary sore, and sometimes even before this has completely disappeared; existing at one time in association with secondary affections of the skin, and at another, and perhaps more commonly, independently of them. From four to eight weeks is the average period of the evolution of the disease when it attacks these structures. What is very remarkable is the extent of surface over which it may spread, there being no visible portion of the mucous membranes upon which it has not been observed. The parts, however, which are most prone to suffer are the tonsils, palate, pharynx, tongue, cheeks, and lips. It rarely extends into the windpipe. No dissections of a satisfactory nature have been made tending to show that the lining of the stomach and bowels ever participates in the morbid action, but it is certain that well-marked signs of the malady have been repeatedly witnessed at the anus, and in the lower part of the rectum within the first inch or inch and a half of that tube. In the male secondary phenomena sometimes appear upon the foreskin and head of the penis, while in the other sex they are liable to occur upon the vulva, vagina, and uterus. Their presence has not been detected in the respiratory and urinary organs, and is, therefore, altogether a matter of conjecture, to be settled by future observation. From the remarkable relations existing between the skin and mucous membranes, and the fact that syphilitic affections of the former are liable to occur in all parts of its extent, it is not improbable that the latter may suffer in a similar manner, although perhaps not in an equal degree, some portions almost entirely escaping, while others are peculiarly prone to receive and harbor the specific virus.

Secondary affections of the mucous tissue occur in various forms; at one time, or in one place, as an erythematous disease, at another as an elevation or tubercle, and, again, as a distinct ulcer, crack, or fissure; depending, doubtless, upon some peculiar modification of the structure of the suffering part, some change in the action of the poison, or some idiosyncrasy of the individual. In the mouth and throat, where these affections are most common, it is not unusual to notice their coexistence, mere inflammatory redness with or without plastic deposit going on at one point, ulceration at another, and the formation of a tubercle or mucous patch at a third.

Syphilitic *erythema* is observed chiefly in the throat, affecting the arches of the palate, tonsils, uvula, pharynx, and perhaps the root of the tongue. In rare cases it extends to the roof of the mouth. It may present itself as a diffused inflammation, or in the form of distinct patches, generally of a circular or oval figure, from the size of a gold dollar to that of a twenty-five cent piece, the intervening surface being apparently quite healthy. The color, in the early stage of the disease, resembles that of a new copper coin, but it gradually loses its bright, fiery hue, shading off into dark bronze, as the morbid action declines. In cases of long standing and unusual severity, the discoloration is of a deep flesh-color and conjoined with marked thickening of the mucous membrane, along with a tendency to ulceration. Deposits of lymph are not uncommon upon the inflamed surface, even when the disease is not at all active; occurring in small aphthous-looking specks, in patches of considerable size, or in circular rings, more or less firmly adherent, and of a pale orange tint.

This affection which bears the closest resemblance to erythema of the skin, generally exists without the consciousness of the patient, as there is no soreness of the throat, difficulty of deglutition, or constitutional disturbance. All is quiet and passive, the discovery of the disease being perhaps purely accidental. . It of course denotes only a very slight taint of the system. It is liable to appear within the first four or five weeks after the primary sore, and, consequently, not unfrequently before this is healed.

Ulcers of the throat assume various appearances, and involve different structures, but more particularly the uvula and tonsils, arches of the palate and back of the pharynx, affecting these parts either separately or conjointly. They occur principally in two varieties of form, the superficial and excavated.

The superficial ulcer is frequently multiple, several occurring together, either in close proximity, or scattered over the inflamed surface. Its appearance is either that of an erosion, or of a cavity with well-defined, ragged edges, rather sharp, and often somewhat undermined: its surface is covered with a white, yellowish, or greenish, tenacious and adherent lymph: the parts around, although red and irritated, are free from induration. The most common sites of this variety of sore, which now and then assumes a serpiginous character, are the arches of the palate, uvula, and pharynx. It generally comes on early after the appearance of the primary sore, and often coexists with it.

The excavated ulcer looks, as the name denotes, as if it had been made with a punch, or dug out of the tissues with a sharp instrument. Its edges are steep, everted, or ragged, like those of the Hunterian chancre, and they are surrounded by a hard, inflammatory, copper-colored base. The surface is usually encrusted with a greenish, muddy, or yellow-ish lymph, which gives it a foul, unhealthy aspect. The discharge is thin and ichorous. The excavated sore is always most distinctly marked on the tonsils, where it sometimes acquires an immense size, and is generally accompanied by extensive inflammation of the surrounding parts. It is often seen during the progress of the primary disease, and is liable to be associated with some of the earlier forms of cutaneous eruptions, particularly the exanthematous and scaly.

Secondary syphilitic ulcers of the throat are liable to phagedenic and gangrenous action, in the same manner as primary sores, and apparently from similar causes, the state of the system and mode of life of the patient mainly contributing to change their character. From the superaddition of this action, extensive destruction of the soft palate may result, followed by difficulty of deglutition and important alterations of the voice. Ordinary syphilitic ulceration of the throat, even when considerable, is not always attended by well-marked local and constitutional symptoms; the disease, in fact, is often remarkably insidi-ous in its approaches, and may, therefore, have made great progress before its presence is even suspected. The excavated form of the affection is generally accompanied with extensive swelling, pain, and difficulty in swallowing, enlargement of the cervical lym-phatic glands, and more or less febrile disturbance. When the tonsils are the seat of the lesion the tumefaction may be so great as to cause serious obstruction to respiration.

Small ulcers, crevices, and fissures, of a secondary nature, are sometimes met with on the lips, especially at the corners of the mouth, the insides of the cheeks, and on the tongue; generally superficial, indisposed to spread, and attended with but little uneasi-ness and discharge. Occasionally they have abrupt edges and a hardened base. Their diagnosis must necessarily be difficult, the only reliable sign being their coexistence with other marks of syphilis, either primary or secondary.

Mucous *tubercles* occur most commonly upon the tongue, lips, inside of the cheek, ton-sils and palate, as slight elevations of the mucous surface, generally of an irregular oval or elongated shape, and of a whitish hue, as if the secretion of the part had been discolored with nitrate of silver or partially coagulated albumen. Upon taking hold of them with the thumb and finger they are found to be more or less hard, not unlike indurated chancres, and remarkably tolerant of manipulation, even firm pressure rarely causing any decided pain. The size of the spots is variable, ranging from a pea up to that of a twenty-five cent piece; they sometimes exist in considerable number, and then they occasionally become confluent. If unrestrained, they may give rise to ulceration, either superficial, or of a deep, excavated character, with steep, callous edges.

This variety of syphilitic affection finds its analogy in the condylomatous excrescences which are so liable to form about the anus, perineum, and vulva, from the action of the syphilitic virus. As it usually comes on without any pain, its discovery is often purely accidental. The most reliable diagnostics are the peculiar color and feel of the affected part above referred to, and the coexistence of syphilis in other localities, particularly the throat and skin. Not unfrequently traces of the primary disease will be found either in an open sore, or in the indurated cicatrice of a recently healed chancre.

In the female mucous tubercles are frequently met with on the inner surface of the labia and nymphæ, the vagina and uterus, forming whitish, grayish, or opaline spots, of an elongated, ovoidal shape, coming on soon after the appearance of the initial sore, and often terminating in ulceration, sometimes superficial, at other times deep. Fully one-half of the women who suffer from constitutional syphilis are affected with mucous tuber-cles of the genital organs. Patches of this kind are occasionally found between the toes, behind the ears, on the perineum, on the scrotum, and, above all, around the anus. Of 130 cases of this disease in men, reported by Bassereau, 110 occurred in this situation. In women it is most common on the vulva. The infectious character of these bodies has been clearly established by experiments and clinical observation.

Treatment.—These mucous affections being all of a kindred character, their treatment must be conducted upon the same general principles. If the patient be at all plethoric, antiphlogistics will probably be necessary, blood being taken either by the lancet or by leeches from the vicinity of the inflamed parts, and the depletion followed by active purgation and the use of antimonial and saline preparations, rendered anodyne and dia-phoretic by the addition, to each dose, of a small quantity of morphia. Light diet and

perfect quietude are enjoyed. In the milder cases of these diseases the most simple constitutional means will generally suffice, no drain upon the system of any kind being necessary.

The most suitable local remedies are nitrate of silver in substance, or acid nitrate of mercury, variously diluted, and applied at longer or shorter intervals, according to the exigencies of each particular case. The first of these articles generally answers best in my hands when there is no breach of continuity, the affected surface being carefully touched once every forty-eight hours, some mildly astringent gargle, or simple mucilaginous fluid, being employed in the intervals. When the part is ulcerated the caustic must be used more boldly, as well as oftener; although, under such circumstances, I usually give a decided preference to the acid nitrate of mercury, diluted with eight or ten times its bulk of water, and applied very gently by means of a large camel-hair pencil, or a very soft linen mop. Not only the sore, but also the inflamed surface around, should be treated in this way, regularly every twenty-four hours, until there is a decided improvement in the disease. Hardly any secondary ulcer of the throat, or tongue, can withstand such a remedy beyond six or eight days, while in many cases it yields in a much shorter time. As soon as the reparative process begins, the acid is used less frequently and in a much more diluted state. When the acid nitrate of mercury is not accessible, a good substitute will be found in nitric, carbolic, or hydrochloric acid. Sulphurous acid, one drachm to the ounce of water, used in the form of a spray, is also a valuable local application.

The gargle which I usually prefer in ulcerated sore throat is a mixture of pyroligneous acid and water, from one to two drachms of the former to half a pint of the latter, well sweetened with honey, and used five or six times in the twenty-four hours. Weak solutions of subacetate of copper and tannic acid, of tannic acid and glycerine, of nitric acid, and of chlorinated sodium also answer an excellent purpose.

Mucous tubercles generally yield to a few applications of solid nitrate of silver, aided by astringent gargles, suitable purgation and light diet. Similar means usually suffice for the cure of superficial abrasions, excoriations, and fissures of the lips, cheek, anus, vagina and anus.

Mercurialization is necessary only in particular cases. The remedy is generally called for when there is an excavated ulcer, or an ulcer possessing an extraordinary degree of indolence, or indolence and induration. The simple, superficial sore rarely requires such a remedy; and it is of course withheld when there is a tendency to phagedena or gangrene in a broken, anemic state of the system. Under such circumstances tonics, a generous diet, and nutritious drinks, with change of air, take the place of mineral.

SECT. IV.—TERTIARY SYPHILIS.

1. GENERAL CONSIDERATIONS.

When the specific poison has deeply penetrated the system, and is, as it were, inlaid in its different structures, as well as thoroughly commingled with the blood, the effects which it produces constitute what is denominated tertiary syphilis. The boundary line, however, between the secondary and tertiary groups of phenomena is not always well defined, the former affections often running, by gradual and insensible gradations, into the latter; an occurrence which cannot be too strongly weighed, on account of its great practical importance. It is generally understood that those symptoms of the disease which show themselves before the fifth or sixth month from the commencement of the primary sore should be classed under the head of "secondary syphilis," while those which come on subsequently, or after this period, are considered as appertaining to the third order of phenomena, or "tertiary syphilis," the average period of their evolution ranging from six to eighteen months, although in very many instances they do not occur until a number of years after the appearance of chancre, or chancre and bubo. Thus, I have repeatedly seen tertiary symptoms manifest themselves, for the first time, from twelve to eighteen years after the primary disease, the poison having lain all this time, like a hidden spark, in the economy. In one of my cases as many as forty years had elapsed from the primary inoculation. Once fairly roused, however, into activity, it rapidly extends through the system, completely overwhelming it in its progress, and exploding, with peculiar force, upon certain tissues, textures, or organs, as if it possessed a kind of elective affinity for them.

A fourth order of symptoms—the quartenary—has of late been recognized by certain syphilographers, consisting of certain morbid changes caused by disease of the viscera, as the brain, heart, lungs, and liver, and coming on long after the initial sore. The dis-

tinction, however, is not well founded, inasmuch as this tardy appearance is not peculiar to the viscera, but common to them and other structures, particularly the skin, bones, cartilages, and fibrous membranes.

The textures most prone to suffer in tertiary syphilis are the connective tissue, mucous membranes, periosteum, bones, fibro-cartilages, aponeuroses, tendons, and testicles. All parts of the economy, however, may be involved in the contamination, and it is extremely probable that, in the worst cases, hardly any entirely escape. The affections of the internal viscera, although alluded to by many of the older syphilographers, have been especially investigated by Virchow, Dittrich, Lebert, Gubler, Wilks, Bristowe, Budd, and Moxon, who have ascertained that the changes in the lungs, brain, heart, liver, and other organs are generally of a very grave character, liable to be followed by the worst results, the more so because their approaches and progress are usually so insidious that even their existence is frequently not suspected during life, to say nothing of the impossibility of arresting them by any known treatment, or combination of remedies. The most common of these internal lesions are gummy tumors, foul, ragged-looking abscesses, with imperfectly elaborated contents, softening and pulpy degeneration, and tubercular deposits. Attention has not yet been sufficiently directed to the alterations of the ovaries of women dead of tertiary syphilis; but from the resemblance which exists between these organs and the testes, both in structure and function, and from the fact that the latter are so often involved in the disease, it is extremely probable that it will be found, as our pathological researches are extended, that they frequently seriously participate in the morbid action. The uterus rarely suffers, and the Fallopian tubes have never been found involved in this disease.

The gummy tumor, so common in the more advanced stages of syphilis in the internal viscera, as well as in some other parts of the body, is worthy of special attention, particularly in relation to the progressive changes effected in the inflammatory deposits and in the structures at the seat of the morbid action. The earliest noticeable alteration which it experiences is hyperplasia of the interstitial connective tissue, the cells of which increase in size and number; the new substance next becomes soft and gelatinous, melting down as it were; unhealthy pus is thrown out, and, finally, ulceration sets in. In a second form of the deposit, there is no unusual development of the connective tissue; the cells retain their normal features or they assume the rounded shape of granulation cells, and by degrees undergo fatty degeneration, the original mass being eventually transformed into yellow tubercles, so characteristic of syphilis in deep seated organs.

A section of a recent gummy tumor exhibits under the microscope three distinct zones, the outer of which consists of highly vascular granulation tissue; the second is composed of fibrillated connective tissue; the third, of a yellowish color and firm consistence, is constituted by a mass of cells undergoing fatty transformation. The gummy tumor is sometimes known as the fibronucleated tumor, in reference to its peculiar structure. The term fibroplastic is also applied to it. Its essential features are alike in the different organs and tissues.

Tertiary syphilis is not invariably preceded by secondary symptoms; on the contrary, there are many cases where the disease passes directly from the first to the third order of phenomena, the structures usually implicated in the secondary attack escaping entirely. It is well known, too, that tertiary syphilis is not always preceded by bubo, or appreciable induration of the glands of the groin.

Tertiary symptoms are most liable to occur in persons of intemperate habits, and of a dilapidated constitution, with an impoverished state of the blood. A scrofulous or scorbutic condition of the system also acts as a predisposing cause.

The immediate development of tertiary syphilis is often remarkably influenced by the habits and state of health of the individual. It is impossible to say how long the specific virus might lie dormant in the system if the subject of it were entirely free from the prejudicial influences of surrounding agents. Exposure to cold is usually accused as being one of the most common exciting causes of the complaint, and yet it is notorious that the inhabitants of the South Sea Islands and other tropical regions are extraordinarily prone to all kinds of constitutional syphilis. There can be no doubt, however, that the poison is often fanned into activity by the hardships of our northern winters and by a residence in damp cellars, or moist, ill-ventilated, underground apartments, especially when this mode of life is conjoined with all kinds of dissipation and intemperance, loss of sleep, and an impoverished diet. Although it is extremely probable that no state of the system, however nearly it may approach to the normal standard, can ever entirely prevent the

development of tertiary syphilis, when once the poison has taken full possession of it, yet there can be no doubt that an individual so circumstanced will, other things being equal, be much less likely to suffer than one who is differently situated, or who gives himself up to the unbridled indulgences of his passions.

It is an interesting fact, a fact now generally accepted by syphilographers, that the matter furnished by ulcers, abscesses, and suppurating surfaces, during the progress of tertiary syphilis, is not heteroinoculable, or, in other words, communicable from one person to another. Any doubts that formerly existed upon this subject have been completely dispelled by recent observations. That the matter, however, is autoinoculable is an equally well attested fact. I have myself seen two cases which unerringly point in this direction, and testimony of a similar nature has been repeatedly furnished by other observers. In one of these cases—that of a man, upwards of sixty years of age, long the subject of tertiary syphilis—matter taken from an intractable ulcer of the skin of one thigh, and inserted into the skin of the other, produced, in a short time, all the characteristic features of a syphilitic chancre, which, in its turn, yielded inoculable fluid, and was a long time in healing. The other instance was equally remarkable. A gentleman, forty years of age, in 1851, had a chancre upon the penis, which was cured at the end of five months, leaving merely an indurated cicatrice. In August, 1862, without there having been any constitutional symptoms in the interval, an abscess formed in the left groin, and at length opened spontaneously. The sore not only never closed, but extended in a serpiginous manner round the thigh towards the anus. In April, 1867, his medical attendant inoculated the sound limb with the secretions of this sore, with the effect of a formation of a pustule, which gradually degenerated into a large ulcer, with hard, elevated edges, very painful, and for a number of years utterly indisposed to heal.

It is believed that tertiary syphilis is rarely hereditarily transmissible; but although this may be true in the ordinary sense of the term, it is extremely probable that the offspring of such an individual are, if not actually imperfectly developed, naturally predisposed to various kinds of cachectic affections, particularly scrofula, scurvy, and rickets, by which life is rendered miserable and often cut off prematurely, the constitution being unable to endure the hardships incident to ordinary pursuits.

The *diagnosis* of tertiary syphilis hardly admits of general description. Every case must stand, as it were, for itself. Very frequently one of the first evidences of the disease is the existence of nocturnal pains, a node upon the tibia, a gummy tumor in the subcutaneous connective tissue, an eruption upon the skin, an ulcer in the throat, a fetid discharge from the nose, or an enlarged and indurated condition of the testicle. Most commonly, however, the patient is conscious of declining health; his appetite and strength sensibly fail; the secretions are disordered; the countenance is pallid; the spirits are dejected; and there is occasional febrile disturbance. After these symptoms have continued for an indefinite period, various local affections appear, generally so well marked as to render it impossible to mistake their character. The history of the case will also commonly furnish important light; and in some instances the diagnosis is readily determined by the nature of our remedies, especially the use of the iodides, which, when the malady is syphilitic, never fail to afford prompt relief of the more severe suffering.

The *prognosis* of tertiary syphilis is always grave. Whatever form it may assume, it is extremely difficult to dislodge it effectually from the system, or to effect a radical cure. Relapses are of constant occurrence from the most trivial exposure, or the least disorder of the digestive organs, and few patients, however skilfully they may have been treated, are afterwards ever entirely free from rheumatoid pains, proneness to cold, and stiffness of the joints. In fact, although recovery undoubtedly does occasionally take place, yet in most cases the constitution remains in an enfeebled and crippled condition, remarkably predisposed to attacks of other diseases.

Tertiary syphilis often proves fatal, although not nearly as frequently as prior to the discovery of the use of the iodides, death generally occurring from local irritation and constitutional exhaustion. Many of those who recover are horribly disfigured by pock marks, the partial or complete destruction of the nose and palate, loss of hair, anchylosis of the joints, and other affections.

2. TERTIARY SYPHILIS OF PARTICULAR ORGANS.

Nervous System.—Syphilis of the brain and spinal cord is more frequent than it was formerly supposed to be. I have myself witnessed a number of well-marked examples of it. It manifests itself in different ways, but the forms in which it most commonly appears

are mental imbecility, epilepsy, paralysis, and muscular twitches. The paralysis is usually of the kind known as paraplegia; sometimes, however, it affects also the superior extremities. I lately had under my care a gentleman, twenty-seven years old, who, in consequence of a chancre contracted three years previously, was suffering from palsy of both legs and of the right arm. In 1876, I prescribed for a lady, aged thirty-two, who was affected with hemiplegia and aphasia, from an attack of syphilis two years before. The paralysis is generally preceded by numbness and various anomalous sensations, but sometimes its advent is sudden and unexpected.

These tertiary affections of the brain and spinal cord seldom come on until several years after the primary sore, and the worst examples that I have seen appeared to have been induced by the joint effects of the syphilitic poison and the inordinate use of mercury, eventuating in a deposit of fibrin, the formation of gummy tumors, or the development of tubercles. Occasionally considerable serous effusions occur.

The cerebral lesions in tertiary syphilis are either direct or indirect, depending, in the former case, upon the presence of gummy tumors or gummy exudations, and in the latter upon obliterative endarteritis, especially of the circle of Willis, and upon caries, necrosis, or exostosis of the cranial bones, more frequently the frontal than any other. Gros and Lancereaux have collected the statistics of 31 autopsies of direct cerebral disease, in 7 of which softening of the brain existed, and in 12 true gummy tumors. The anterior lobes are especially liable to suffer from these lesions. Cicatricial furrows, similar to those observed in syphilis of the liver, are sometimes seen upon the surface of the brain. Among the more remote effects of syphilis of this organ, are epilepsy and neuralgia, both commonly of a very intractable character. Symptoms of hysteria and chorea are also of occasional occurrence.

The diagnosis is in general readily determined by the history of the case, the existence of syphilis in other parts of the body, as nodes, sores, eruptions, papules, or tubercles, and the dilapidated state of the system. In paralysis, the attack is occasionally ushered in by symptoms closely simulating those of cerebral apoplexy; the stupor, however, soon disappears, and the concomitant phenomena are of shorter duration. In every one of my cases, the paralysis was associated with exquisite tenderness of the dorso-lumbar portion of the spine, and a want of power in the sphincter muscles of the anus and bladder. It is a noteworthy fact that most of the cases of hemiplegia occurring in early life are due to a syphilitic taint of the system.

The prognosis of this class of affections is generally very grave. They are always difficult of cure, and not a few of the patients perish from their effects; some suddenly, others gradually, apparently from sheer exhaustion.

Syphilitic affections of individual *nerves*, eventuating in disturbances of the special senses, anæsthesia, hyperæsthesia, analgesia, paralysis, or neuralgia, are by no means infrequent, although they cannot always be readily traced to their true source. They may depend either upon disease of the nerves themselves, as when they are infiltrated with gummy matter, upon lesion of the brain at the roots of these cords, or upon disease, as caries, necrosis, or exostosis, of the openings in the bones through which the nerves pass to reach their destination. In all these conditions it is easy to perceive how effectually the transmission of the nervous fluid might be interfered with, causing either neuralgia or paralysis of the most inveterate, if not incurable, description. Many of the more obscure cases of these affections are referable to these morbid alterations, which are by far most common in the cerebral nerves, although the spinal are by no means exempt from them. The syphilitic character of these lesions may be suspected when they coexist with a syphilitic taint of the system.

Syphilis of the Eye and Ear.—*Iritis* belongs to the more advanced stages of syphilis, being usually associated with papular, tubercular, or pustular eruptions, rupial sores, nodes, and rheumatism of the bones, and ulceration of the throat, palate, and nose. Its coexistence with the papular form of the disease is exceedingly common. Of eleven cases, observed by Dr. F. F. Maury at the Philadelphia Hospital, in 1866, iritis and papules were present in every one. The affection is characterized by a fixed and contracted state of the pupil, which is generally filled with lymph and displaced upward and inward; by the appearance, upon the anterior surface of the iris, of reddish-brown tubercles, or minute yellowish abscesses; and by severe nocturnal pains, situated deep in the eye, forehead, and temple. The disease commonly attacks both organs, either simultaneously or successively, and always rapidly extends to the other structures, as the cornea, choroid, and retina, involving them in its ruinous consequences, few persons recovering without loss of

sight.   As allusion will again be made to this affection, and also to syphilitic keratitis, in the chapter on the eye, no further notice need here be taken of them.

Retinitis as an effect of syphilis is uncommon ; it generally makes its appearance within the first eighteen months after the primary sore, and as it is usually unaccompanied by other constitutional symptoms it is exceedingly liable to be overlooked.   The most prominent phenomena are pain in the eye and temple, indistinctness of vision, and a sluggish condition of the pupil.   The retina is seen to be abnormally vascular, more or less hazy, and dotted with little whitish, yellowish, or reddish points, of a globular outline, and closely resembling the condylomes observable in iritis.   Considerable œdema is often present, and the optic nerve is seldom free from involvement.

Syphilitic *choroiditis* is also infrequent ; it rarely exists by itself, but is usually associated with iritis or retinitis, and is characterized by impairment of sight, more or less pain, and other symptoms denotive of inflammation of the deeper structures of the eye. The pathological changes are variable, but the most prominent are an injected and varicose state of the bloodvessels, plastic deposits, and serous infiltrations.   The vitreous humor, retina, and optic nerve are always involved in the more severe forms of choroiditis. Both choroiditis and retinitis are occasionally met with as inherited affections.

The *eyelids*, especially the upper, not unfrequently suffer in tertiary syphilis.   The disease generally occurs as an indurated ulcer, somewhat of an oval shape, commencing at the tarsal edge, and thence gradually extending to the other structures.   The borders are inflamed and thickened, the conjunctival lining is more or less œdematous, and there is considerable muco-purulent discharge.   The diagnosis is founded upon the history of the case, the rebellious character of the sore, the indurated and enlarged condition of the glands behind the corresponding ear, and the coexistence of syphilitic disease in other parts of the body.   The only ulcer with which it is liable to be confounded is the epithelial ; but from this it is usually readily distinguished by the fact that the latter never heals, whereas the former often undergoes repair at one point while it spreads at another.   The diagnosis is often promptly decided by the use of antisyphilitic remedies.

Syphilis of the *ear* is uncommon.   Patients of a broken constitution and of intemperate habits are most likely to suffer from it.   The disease generally comes on in the form of sudden deafness, attended with aching pain, and evidently consists of inflammation of the tympanal membrane, which, upon inspection, is found to be red and abnormally vascular, and, in time, to become more or less opaque.   If the morbid action be not soon arrested it may eventuate in ulceration, followed by complete destruction of the membrane, and by permanent deafness.   In the worst forms of the disease, the Eustachian tube, the middle ear, and even the petrous portion of the temporal bone become involved.

The diagnosis is usually sufficiently easy, the most reliable points being the coexistence of syphilis in other parts of the body, the comparative slightness of the pain, which is much less than in ordinary myringitis, and the amenability of the disease to specific treatment.   The affection evidently appertains to the earlier tertiary group.

Digestive Organs and Liver.—Tertiary affections of the throat and mouth are by no means uncommon ; they supervene at an indefinite period after chancre, and manifest themselves in characteristic ulcers, which, if permitted to go on, gradually spread to the palate and maxillary bones, which, together with the soft parts, are sometimes destroyed to a most frightful extent, the buccal and nasal cavities being perhaps laid into one immense cavern.   In some of these cases large portions of the alveolar process of the maxillary bone are necrosed, followed by the loss of many of the teeth, and a similar fate may be experienced by the ascending process and ungual bone, thus implicating and endangering the lachrymal sac and its canal.   The nature of the disease is readily ascertained by inspection and by the altered state of the voice and breath.

Tertiary syphilis of the *tongue* generally appears in the form of ulcers, or fissures, the latter of which are sometimes of enormous extent and depth, reaching far into the substance of the organ.   Specific ulcers are usually situated upon the side of the tongue, at or near its middle, and exhibit the characteristic features of venereal sores in other structures, having a deep, excavated form and a foul surface, with marked induration of the base, the parts feeling, on being pinched, like a mass of fibro-cartilage.   Only one such cavity generally exists, and this, when large and irritable, may give rise to a swelling of the lymphatic glands at the base of the jaw.   The history of the case, the foul, excavated character of the sore, and the existence of syphilitic disease in the throat, nose, or other parts of the body, will always distinguish the lesion from other affections.

Mucous tubercles are occasionally met with, and gummy tumors are not uncommon ; they are generally situated near the base of the organ, deep among the muscular fibres,

and usually rapidly disappear under specific treatment. The more superficial sometimes ulcerate, forming foul, ill-conditioned sores, with a tendency to spread in different directions, and often difficult to heal.

The following case, that of a man twenty-eight years of age, a patient at the College Clinic, affords an excellent type of the tertiary form of this disease in this situation. The tongue, which was of the natural length and breadth but much increased in thickness, and excessively hard at the sides, especially the left, was covered with numerous fissures, of varying size and depth, overhung by steep, indurated edges, which at first sight concealed them almost completely from view. The largest groove, which resembled a deep furrow, extended along the centre of the organ, from a short distance in front of the root to within a few lines of the tip, its depth being nearly half an inch. The bottom of each fissure had a clean, smooth appearance; and there was an entire absence of pain and even of soreness under rough manipulation, although the mucous membrane of the tongue generally was somewhat redder than naturally. The starting-point of the disease seemed to have been the throat, which had been inflamed for a long time; the uvula had become elongated, and had been cut off weeks before. The arches of the palate and the tonsils were still a good deal discolored and congested. The tongue had been in its present condition for three months, having resisted various kinds of treatment, without the disease apparently manifesting any tendency to spread. A small, painful node existed on the right tibia, and there was a vesicular eruption with some itching on the face. Under the internal use of iodide of potassium with bichloride of mercury, and the local application, every other day, of solid nitrate of silver, the man rapidly recovered.

Serious disease of the *teeth* sometimes occurs in tertiary syphilis. It generally manifests itself in the form of a black spot, in the upper incisors, upon the anterior surface of the enamel, close to the gum, and gradually extends until the crown separates from the fang. In time, the lower incisors suffer in a similar manner.

Gummy deposits have been found in the *œsophagus*, terminating in a bad form of ulcer; in other cases the syphilitic disease excites stricture of this tube, as I have myself witnessed in three remarkable instances. These affections always come on long after the primary sore. The history of the case is generally the best interpreter of its nature.

Syphilitic ulceration of the *intestines* is an occasional cause of long-continued dysentery, attended with bloody, mucous discharges, more or less pain, and excessive emaciation. The parts most commonly involved are the colon and the small bowel near the ileo-cæcal valve. Syphilitic stricture of the rectum and anus will be described in a future chapter.

The *liver* is, perhaps, more frequently affected in tertiary syphilis than any other organ, the lung not excepted. The most important anatomical alterations are gummy tumors, or gummy and fibrinous infiltrations, and cicatricial furrows, grooves, or scars upon the surface of the organ. The gummy tumors are of variable size and form, and generally most numerous at the periphery of the liver. They usually coexist with evidence of syphilis in other parts of the body, and generally come on at a very remote period, at ten, fifteen, or even twenty years after the primary affection. There are no symptoms by which they can be distinguished during life from the more ordinary diseases of the liver.

Syphilis of the Heart and Respiratory Organs.—The lesions of the heart and large vessels, consequent upon tertiary syphilis, are imperfectly understood. The subject has been studied with much attention by Virchow, and interesting cases have been reported by Ricord, Lebert, Robert, Gubler, and others. The most important anatomical changes, in the earlier stages of the disease, are fibrinous, albuminoid, or fatty infiltration of the muscular fibres of the heart, interspersed with numerous molecular granules; and, in the more advanced periods, gummy deposits either in the substance of the organ or upon its free surface. Whitish, yellowish, or drab-colored spots, the result of inflammatory action, are occasionally seen upon the endocardium and pericardium. Syphilitic disease of the heart is generally associated with similar affections in other parts of the body, especially of the lungs and liver. The specific degeneration has been noticed in various parts of the arterial system, and is now universally regarded as a predisposing cause to aneurism. Disease of the heart will probably eventually be found to be more common in inherited than in ordinary syphilis.

Syphilitic disease of the *nose*, or syphilitic ozena, as it is occasionally called, manifests iteslf in inflammation and ulceration of the pituitary membrane and of the different bones of the nasal fossæ. In the more severe forms of the affection the proper bones of the nose not unfrequently suffer. The morbid action, which is generally associated with marks of a constitutional taint in other situations, usually sets in at a very remote period

after the primary sore, and lingers on obstinately for many years, notwithstanding the best directed efforts to arrest it, until it has caused the most extensive havoc, piece after piece dying and dropping off until every one has disappeared. When the proper nasal bones are involved, the whole organ, bridge, cartilage, and skin may be destroyed. The disease is attended with an abundant fetid and bloody discharge, and the voice has a peculiarly characteristic, muffled twang. The septum often suffers in this form of syphilis, giving way, first, at the cartilaginous structure, and afterwards at the osseous. Openings, of variable size and shape, are thus formed, with sharp, irregular edges, which have a constant tendency to enlarge until the greater portion of the septum is destroyed.

Syphilis of the *larynx* seldom comes on until a long time after the primary sore, and may, therefore, very properly be classed among the tertiary phenomena. Although it may occasionally be simply an extension of disease from the palate, tonsils, or pharynx, it usually occurs as an independent affection, commencing in the larynx, and thence sometimes passing up into the throat. Its coincidence with syphilis in other parts of the body, particularly of the skin, bones, and fibrous membranes, sufficiently stamps its character, and renders it easy of diagnosis.

The relative frequency of the localization of syphilis in the larynx is undetermined. Gerhardt and Roth detected it in this situation in 18 cases out of 56. One-half of the cases occurred in the third decennium of life. The malady appears to be equally common in both sexes, but is very rare in children.

The disease, beginning in inflammation, soon terminates in ulceration, which often continues for months and even years together, the erosive action being at one time stationary, or on the very verge of healing, and at another steadily advancing. Confined originally to the mucous membrane, it at length invades the arytenoid cartilages, the vocal cords, and even some of the muscles of the larynx. Portions of the thyroid cartilage occasionally perish, and a not uncommon occurrence is the partial destruction of the epiglottis. In some of the cases of this disease that have come under my observation, nearly the whole of the epiglottis was eaten away, nothing but a thick, narrow, stump-like remnant being left, as seen in fig. 81, from a preparation in my private collection. The cricoid cartilage rarely participates in the disease.

Fig. 81.

Syphilitic Ulceration of the Larynx.

The ulcers are seldom numerous, unless they are follicular, when the affected surface is occasionally literally studded with them; generally there are not more than one or two, which are then pretty large, both as it respects their depth and superficial area. They are of a circular or oval shape, with indurated edges and a foul bottom, and, in the more severe and protracted cases, they sometimes penetrate very deeply, opening, perhaps, externally. Such an occurrence is most probable when there is extensive destruction of the thyroid cartilage.

Occasionally the mucous membrane, instead of being ulcerated, is covered with granulations, warts, or excrescences, of a red, fleshy color, from the size of a small pin-head to that of a mustard seed, their number varying from half a dozen to fifteen or twenty; they are usually most conspicuous around the vocal cords, and apparently consist in a hypertrophied condition of the mucous crypts which naturally exist in the interior of the vocal tube. Sometimes the disease manifest itself in the form of distinct nodules, gummy tubercles, or condylomatous excrescences with a broad base. In a case which I recently examined, one of the sinuses of the larynx was completely annihilated, while the other was closed up by a fibroid tumor. The patient, a man fifty-three years of age, had not been able to speak above a whisper for several weeks before his death.

The symptoms are generally well marked, particularly when the disease has made considerable progress, or when it presents itself in the form of ulceration. Besides the wan, emaciated, and cachectic appearance of the patient, which is itself almost sufficient to point out the nature of the affection, there is a hoarse, husky characteristic state of the voice, which is gradually reduced to a mere whisper, and eventually completely lost. The larynx feels tender on motion and pressure; deglutition is difficult and painful; and

the slightest vocal exertion is productive of severe suffering. Cough is always present, frequently to a most harassing extent ; and in attempting to swallow fluids the patient is frequently seized with paroxysms of impending suffocation. The expectorated matter is excessively fetid, often bloody, and occasionally mixed with fragments of cartilage, its quantity being frequently very copious. As the disease progresses, the local and constitutional irritation increases ; the emaciation becomes extreme ; the sweats are copious ; and the patient finally dies completely exhausted, the immediate cause of death being, perhaps, inanition, suffocation, or hemorrhage from the sudden giving way of an important artery. The precise seat and extent of the morbid action can only be determined by laryngoscopic inspection.

The prognosis is variable. The milder cases often yield to treatment, whereas the more severe are generally incurable, especially when attended with a dilapidated state of the system. Syphilitic ulcers are always followed by permanent loss of substance, and by radiating cicatrices, hard, dense, and firm, with a disposition to contract and to cause constriction of the tube. In the vocal cords and arytenoid cartilages they invariably lead to irremediable alterations of the voice, not unfrequently amounting to complete aphonia.

Syphilitic involvement of the *lungs* is uncommon. The disease generally occurs in the form of gummy tubercles, either single or grouped, of variable size and shape, of a dirty grayish color, and, in their earlier stages, of a tolerably firm consistence. The tubercles sometimes exist in large numbers, and are then not always easily distinguishable from ordinary scrofulous tubercles. The matter which is formed during their disintegration is of an unhealthy character, and often remarkably fetid and putrilaginous.

The trachea and bronchial tubes are sometimes inflamed, ulcerated, and even seriously strictured in this disease ; the bronchial lymphatic glands are also liable to suffer, and the pleura is occasionally studded with tubercles and covered with sero-purulent effusion.

The diagnosis is deduced from the history of the case, the presence of cough, the gradual decline of the general health, and the existence of syphilis in other parts of the body.

Urinary and Genital Organs.—The precise character of the syphilitic lesions of the urinary organs is still undetermined. In the kidneys, the most common alteration is interstitial inflammation, attended with gummy deposits, fatty degeneration, and atrophy of the uriniferous tubes, followed by induration of the renal tissue, and deep cicatricial depressions upon the surface of these organs. Occasionally there is amyloid degeneration ; and cases are met with in which the kidneys are tumefied, softened, and of a remarkably pale grayish color, interspersed with little yellowish streaks, dots, or points. The suprarenal capsules are sometimes greatly enlarged, and transformed into fatty matter.

The bladder and ureters are occasionally inflamed, and the seat of plastic deposits. When the disease is chronic, it is very liable to pass into suppuration, especially if it be associated with paralysis of the lower extremities. I lately attended a case of this kind in which the quantity of pus and mucus thrown off in the twenty-four hours was absolutely enormous ; the urine was of a very dark color, and contained, in addition to these ingredients, a large amount of albumen. It was free from odor, and for a long time dribbled off involuntarily, owing to the loss of power in the sphincter muscle of the bladder. Renal casts are often present.

Syphilis of the *testicle* is generally one of the remote effects of this disease. The average period, in the numerous cases that have fallen under my notice, was from two to four years ; but frequently the enlargement does not come on until after the lapse of eight, ten, or even twelve years. It is usually associated with syphilis of other parts of the body, particularly the bones, joints, throat, nose, and skin, the last of which is often extensively ulcerated and otherwise disordered.

The disease almost always involves both testicles, either simultaneously or successively, although seldom in an equal degree ; and, as it proceeds, it is sure to extend to the epididymis, the two structures thus forming eventually one inseparable mass. The swelling is characterized by extraordinary weight and hardness, the affected organ resting upon the hand like a heavy, solid body, and requiring constant support to prevent it from causing a sense of dragging. When the disease has reached its maximum, the testicle is often six to ten times the normal bulk. The surface of the tumor is variable, although generally it is rather smooth, or but slightly knobby. The induration is uniform, except when there is, as not unfrequently happens, an accumulation of water in the vaginal tunic, when the corresponding portion may be soft and fluctuating. The spermatic cord usually

participates in the morbid action, being unnaturally hard and thickened, feeling like a whip-cord when pressed between the thumb and finger. When the disease is of long standing, the affected structures lose their normal characters completely, either at particular points, or throughout, the seminiferous substance being replaced by fibrous tissue. In its worst forms gummy deposits occur, which, breaking down and disintegrating, lead to the formation of unhealthy abscesses and fungous growths.

Syphilitic sarcocele is always a remarkably tardy and painless disease. It is only, as a rule, when there is much water in the vaginal tunic, constituting the complication called hydrosarcocele, and causing constant pressure upon the inflamed and degenerating tissues, that the patient will be likely to suffer much, and then chiefly at night and in damp weather. When the swelling is very large, considerable inconvenience is usually experienced from its weight and bulk. The subjects of this form of syphilis are nearly always thin, pale, and anemic, the appetite is greatly impaired, the strength is wasted, and the sleep is interrupted by nocturnal rheumatism. Their whole appearance, in fact, is indicative of a worn-out, miserable state of the system. When both organs are extensively diseased, the individual must necessarily be impotent. A remarkable feature of this form of syphilis is its tendency to recur, perhaps again and again, after being apparently relieved by treatment.

Syphilitic orchitis is always easily distinguishable from common orchitis, first, by the tardy, indolent, and persistent character of the swelling; secondly, by the simultaneous or successive involvement of both organs; thirdly, by the coexistence of syphilitic disease in other parts of the body, especially of nodes, and ulcers of the skin, nose, and throat; fourthly, by the gradual but certain destruction of the textures and functions of the testicle; and, lastly, by a careful consideration of the history of the case, particularly the character of the patient. When there is unusual obscurity, it is well that the surgeon, before resorting to extirpation, should make a faithful trial of antisyphilitic remedies, otherwise he may have occasion to lament his rashness.

The subjoined case, treated at the College Clinic, affords an excellent illustration of the nature, progress, and termination of syphilitic orchitis, with the changes experienced by the affected organ. The man, aged 29, had, on admission, a fungus of the right testicle, which had commenced, four months previously, as a small pustule on the scrotum. Nine years before he had had a chancre and bubo, and was now laboring under syphilitic rheumatism, ulceration of the tibia, and a slight eruption upon the face. The right testicle had been enlarged, hard, and painful for the last three years; the left one was also diseased, but in a less degree. The general health was much impaired. The fungus was about the size of a half dollar, and the seat of a fetid, ichorous, and profuse discharge, as well as of severe suffering, especially at night. As the organ was hopelessly destroyed, I at once removed it. The tubular structure was completely annihilated, a fibrous substance, of a pale yellowish color and dense consistence, occupying its place. At the posterior part of the epididymis was an abscess, about the volume of a small hickory-nut, filled with a tough, yellowish, cheesy-looking matter, bearing a close resemblance to tubercular deposit. The wound soon healed, and under the use of iodide of potassium and bichloride of mercury, aided by a generous diet, the patient rapidly improved in health and spirits. Whenever syphilitic orchitis is of long standing, whether it be accompanied or not by fungus, the tubular substance will generally be found to be irretrievably destroyed.

The seminal vesicles and prostate gland rarely suffer from syphilis. The deferent tubes, on the contrary, participate in the morbid action, for the most part in conjunction with disease of the epididymis and testes, feeling like hard, firm cords under the skin. In the cavernous bodies of the penis gummy nodes sometimes form, commencing as small, painless lumps, nearly always situated in the posterior third of the organ, where, as they increase in volume, they occasion more or less deformity, and may so completely interfere with the circulation of the blood as to render intercourse impracticable.

Tertiary syphilis is sometimes met with in the breast, either in the form of distinct gummy tumors, or as a diffused indurated condition of the entire gland. The ovaries, uterus, and vagina are occasionally affected, but no disease of this kind has, I believe, ever been noticed in the Fallopian tubes.

Skin.—Ulcers of the skin, which may commence as ecthyma, rupia, or softened gummy tumors, are usually among the more remote effects of the tertiary form of the disease, coming on, in most cases, several years after the primary affection. They usually coexist with nodes and rheumatic pains, or with ulcers of the throat, nose, and larynx, or with all these ailments combined, and are nearly always preceded by scaly eruptions, pus-

tules, papules, or tubercles.   Persons of a broken, infirm, and cachectic constitution are their most common subjects, and those in whom they commit the greatest ravages.

Much diversity exists in regard to the situation and character of these cutaneous ulcers. They are most frequently found on the extremities, especially the inferior ; they are also sufficiently common on the forearm and elbow, and on the scalp, forehead, and temple. Their size ranges from a split pea to that of the crown of a hat, their shape being usually circular or oval, although sometimes it is extremely irregular from two adjoining sores being connected or running into each other. The edges are nearly always callous, everted, and more or less ragged ; the surface is excavated, covered with a greenish, pultaceous matter, and exquisitely sensitive ; while the discharge, which is often very profuse, is thin, ichorous, and offensive, frequently excessively so. In other cases the sore is covered with a brownish-black or greenish-black crust, which may be flattened and depressed, or conical and laminated. It is not often that there is anything like a distinct, well-defined areola ; such an occurrence is very rare, but in most instances there is marked inflammation with redness and induration in the parts immediately around. The largest of these ulcers generally occur on the shoulder, side, and buttock, and it is amazing what an immense size they may attain. Numerous small ulcers of this kind occasionally exist in groups, giving the surface a peculiar worm-eaten appearance. In some cases, again, the ulcers have a serpiginous arrangement ; in another class of cases they are, perhaps, very much undermined ; and now and then two large ulcers are connected together by a kind of cutaneous bridge. In fact, there is no end to the diversities of their configuration. Finally, they may be quite superficial, or so deep as to involve the subjacent connective tissue, and even the fasciæ, muscles, tendons, and bones. Rupial ulcers of the skin are admirably illustrated in fig. 82. The diagnosis is unmistakable.

Fig. 82.
Rupial Ulcers of the Skin.

Syphilitic ulcers often continue for an indefinite period, sometimes partially cicatrizing, now spreading, now indolent, or stationary.   From local causes, as well as constitutional, they may take on almost any kind of action : when the patient is in an exhausted, irritable condition, they are very apt to become severely inflamed, and to assume a phagedenic, sloughing character, often spreading with immense rapidity, both in diameter and in depth. The system generally actively sympathizes with these sores, the skin being hot and dry, the pulse small, quick, and frequent, the appetite impaired, the sleep destroyed, and the loss of flesh and strength excessive. The patient has an old, superannuated, careworn look, with all the signs of a deep-laid syphilitic cachexia. The scars left by the healing of these ulcers are abnormally white, and retain for a long time a remarkable hardness, with a tendency to constant furfuraceous desquamation. They are sometimes very rough, and prone to reopen from the slightest causes.

The diagnosis of a syphilitic ulcer of the skin is generally sufficiently easy, the only affection with which it is liable to be confounded being the common non-specific sore. Its very appearance, in fact, usually at once stamps its character.   In the first place, it is ordinarily circular or oval, and of an excavated shape, with hard, everted edges, and a foul surface, destitute of granulations and of healthy discharge ; the surrounding surface is indurated, and nearly always somewhat of a copper, bronze, or brownish color. Secondly, the sore is often multiple, occurring in groups, and also on different parts of the surface, a circumstance which is generally of itself sufficient to denote its nature ; for the ordinary ulcer is usually solitary, and is most common on the lower extremity. Thirdly, the disease of the skin nearly always coexists with syphilitic disease in other structures, especially of the periosteum and bones. Finally, the effects of the treatment afford important aid in doubtful cases ; ordinary ulcers disappearing, or soon assuming a healthy, granulating condition, under simple antiphlogistics, rest, and light diet, whereas specific ulcers always require the use of the iodides and of mercury, the latter often both internally and externally.

Syphilitic eruptions are sometimes attended with *onychia*, or inflammation of the matrix of the nails, the latter of which gradually become dry and black, and eventually drop off, leaving a foul, excavated, painful ulcer, with hard, steep edges, and a very fetid, ichorous discharge. If the morbid action be very severe, or not soon checked, the matrix will be completely destroyed; most commonly, however, a part of its substance survives, and afterwards makes a feeble effort at the formation of a new nail, generally an ill-shaped, stumpy, horn-like excrescence, wholly different from the original structure. The diagnostic signs of the disease are the copper-colored appearance of the surface immediately around the ulcer, and marks of syphilis in other regions of the body. The lesion occasionally does not appear until many months after the primary sore, thus bringing it, properly speaking, under the head of tertiary symptoms. It is most common in children, as a result of inherited syphilis.

In what is called friable onychia, the nail gradually loses its natural lustre, assumes a dull, yellowish color, becomes thickened at the edges, and readily breaks or cracks, large portions often dropping off on the slightest exposure. The skin under and around the nail is generally much thickened. Hypertrophy of the end of the finger, or even of the entire finger or toe, is a sufficiently common occurrence, especially in inherited syphilis.

Condylomes of the skin, or of the skin and mucous membrane, usually described by the French syphilographers under the name of mucous tubercles, consist of various sized excrescences, of a flat and rather broad appearance, occurring either in groups or as isolated growths, dependent essentially upon a hypertrophied condition of the integument. It is difficult to assign to this disease its precise rank in the order of syphilitic phenomena, or even to affirm, with certainty, that it is always plainly of a syphilitic character. Surgeons of great experience do not hesitate to assert that condylomes may be produced by the contact of gonorrhœal matter, or by acrid vaginal and other non-specific secretions. On the other hand, it has been alleged that they pertain, not to one form of syphilis, but to all three, now following chancre, now secondary syphilis, and now tertiary. As for myself, I am inclined to regard them as belonging rather to the third order of phenomena than to the second, and under no circumstances whatever to the first.

These excrescences are sometimes the result of hereditary syphilis, as I have witnessed in a number of instances. In one remarkable case—that of a lad eight years old—the father had had a similar affection several years previously, in consequence of tertiary syphilis, attended with nodes and scaly eruptions. The tubercles occupied the margin of the anus and the lower part of the perineum, the child being pale and thin, but there was no other evidence of constitutional contamination. The mother had given birth to three infected infants, two before, and the other at the full period; the former were cast off dead, in a putrid condition, and the latter died at the age of three months from marasmus, the whole body having been covered with scaly eruptions, which were particularly conspicuous on the forehead, hands and feet. All the other cases were equally well marked.

The most common sites of condylomes, fig. 83, are the scrotum, perineum, anus, buttocks, and vulva. They also occur, although rarely on the penis, and in the folds of the thigh, in the axilla, and in and around the ear, and between the toes. They have a particular predilection for parts

Fig. 83.

Condylomes.

which are habitually hot and moist; for it is there that they are not only most frequently found, but that they acquire their greatest and most rapid development. Their size and shape are very various. Thus, they may, on the one hand, not be larger than a pin-head, or a mustard seed; while on the other, they often acquire the volume of a filbert, and

even of a small almond. In shape, they are usually flat, with a broad base, although not unfrequently the free portion is much larger than the adherent, a circumstance which gives the growths a pedunculated aspect. When they occur in groups, as is very apt to be the case, they often coalesce, forming thus considerable masses, tuberculated on the surface, irregular in shape, of a reddish color, and of a firm, fibrous consistence. The largest and worst of these tumors always occur at the margin of the anus, and on the perineum, vulva, and other parts which, from the contact of the opposing surfaces, are habitually subjected to friction, heat, and moisture, which, as already stated, are greatly conducive to their development. In these localities, the tumors are always humid, exhaling a thin, muco-purulent fluid, often very abundant, and always excessively fetid. In those parts, on the contrary, where they are more exposed to the air, they are dry, insensible, of a darkish color, and partially incrusted with scabs.

Condylomes often coexist with other evidences of a syphilitic taint, especially nodes, ulcers, tubercles, and scaly eruptions of the skin. Their course is variable ; sometimes steadily onward, at other times stationary, and now and then even retrogressive. Exercise and friction always irritate them, rendering them sore, and more or less sensitive, if not actually painful. When they are large and numerous, the discharge is generally copious, almost insupportably offensive, contagious, and consequently inoculable. They are rarely accompanied by febrile symptoms.

The diagnosis cannot be mistaken. The situation of the excrescences, their peculiar shape, their chronic character, and their fetid secretions all serve to impart to them a distinctive character. Corroborative testimony is often furnished by the history of the case and by the presence of syphilis in other parts of the body.

Connective Tissue, Muscles, and Tendons.—Gummy tumors, of variable size and shape, are liable to form in the subcutaneous connective tissue during the progress of this disease, especially in persons of feeble constitution or broken health. They evidently appertain to the third group of phenomena, are usually very indolent, and seldom, in their earlier stages, encroach upon the skin. In volume they range between that of a pea and a pullet's egg ; they are of a firm, semielastic consistence, and they not unfrequently occur in considerable numbers, several being occasionally seen side by side. Commonly, however, there are not more than three or four, situated perhaps at remote points. In a case under my charge at the Philadelphia Hospital there were two on the chest, one on the clavicle, and one in the hyoid region, the rest of the body being entirely free from them. Perfectly movable at first, they gradually contract adhesions to the surrounding skin, and ultimately suppurate and ulcerate, discharging a thick, gummy matter, whence their name.

Sometimes successive crops of these tumors occur, one disappearing as another arises, and thus the disease is occasionally kept up for months and even years. The resulting abscesses may be very small, and then they are generally proportionately numerous. I have witnessed cases in which hundreds, not larger than a pea, were scattered over the chest, arms, and shoulders.

Gummy tumors occasionally form in the muscles and tendons, generally in connection with syphilitic affections in other parts of the body, as ulcers of the skin or fauces, nodes, exostoses, and tumors of the connective tissue. They range in volume from a pea to that of a pullet's egg, are of a firm, dense consistence, and are seldom attended with severe pain, except when they are breaking down and becoming disintegrated. They are most easily detected by their peculiar feel when the muscles and tendons are relaxed.

The diagnosis of gummy tumors is usually easily determined by their situation, by their semielastic feel, by their coexistence with syphilis in other parts of the body, by their tardy progress, by their tendency to disintegration, and by their history.

Osseous and Fibrous Tissues.—Affections of the periosteum and bones belong to the later order of tertiary syphilis, and they may declare themselves in various forms, of which the most important are nodes, or gummy tumors, inflammatory hypertrophy, exostosis, caries, and necrosis. These affections may come on at any time after the eighteenth month from the date of the initial sore, but in the great majority of cases they do not arise until after the lapse of at least twice that period. They are most liable to occur in persons of a scrofulous and cachectic constitution, and in those whose health has been destroyed by habitual intemperance, constant exposure, and deficient alimentation, leading to an impoverished state of the blood and protracted derangement of the secretions. The idea is now generally prevalent that diseases of the periosteum and bones, especially in their more severe forms, are, in great measure, limited to those persons who have undergone

severe courses of mercury for their cure ; and in this opinion the results of my experience fully concur.   Of the many cases of tertiary syphilis of the osseous tissue which have fallen under my observation nearly all had taken mercury in large quantity, and the few who had been treated without that remedy had suffered comparatively little, except where there was a marked strumous diathesis, which never fails to aggravate the effects of the ingrafted disease.   It would thus appear, at first sight, that this mineral, by combining with the specific poison, was capable of essentially modifying its action, if not of forming a new virus, more potent and destructive than the original.   However this may be, it is certain that the action of mercury, when carried to excess, is a most powerful depressant, the effect of which is felt, for a long time, by the whole system, by the blood not less than by the solids.   A species of physical degradation of the entire organism is thus engendered, which strongly predisposes it to the injurious operation of morbific agents, whether acting within the system, or impressing it from without, through the medium of the cutaneous and mucous surfaces.   Instead, therefore, of supposing that a new poison, or a sort of a syphilitico-mercurial virus, is formed under these circumstances, it will be found to be more in accordance with the established facts of pathology to conclude that the frightful ravages so often committed in tertiary syphilis, after the inordinate use of mercury, in the osseous tissue, are the result, exclusively, of the deteriorating influence of this mineral upon the general system, whereby the more feebly organized structures, as the bones and their investing membrane, are rendered peculiarly prone to the occurrence of a bad form of inflammation, which, if not early checked, often leads to the most disastrous consequences.

Tertiary syphilis is met with only in certain bones, chiefly in the superficial, or in those least protected by soft parts, as the tibia and fibula, ulna, clavicle, and bones of the skull, nose, palate, and upper jaw.   In rare cases, almost every piece of the skeleton is involved, either simultaneously or successively ; some in nodes, some in caries, some in necrosis, and some in exostosis.

Nodes occur principally upon the tibia, the ulna, the clavicle, and the skull, particularly the frontal and parietal bones, as in fig. 84, from Jullien. Apppearing as circumscribed, semisolid swellings, they are of an ovoidal shape, somewhat elastic to the touch, and from half an inch to an inch and a half in diameter.   So far as we are able to determine, they always begin beneath the periosteum, upon the surface of the bone, in the form of a gummy tumor.   The periosteum and bone at the seat of the node, are inflamed, softened, and ulcerated ; and, as the tumor extends, the superincumbent structures, participating in the morbid action, become red and painful, and ultimately yield at the most prominent point, thus allowing the pent-up fluid an opportunity of escaping, although generally in a very imperfect manner, and not without severe suffering.

A node is essentially a broken-down gumma. Its course is always chronic, and the attendant pain is peculiar, being of an intermittent, neuralgic character, subject to violent nocturnal exacerbations.   The general health is usually disordered,
Fig. 84.

Nodes of the Skull.

and, if the swelling is large, there is apt to be considerable constitutional disturbance. Nodes often coexist in different pieces of the skeleton, the skull, for example, being sometimes literally studded with them.

An ulcerated node may take on an almost endless variety of morbid actions, incident to syphilis in other structures.   Thus, it may be excessively irritable, be invaded by phagedena or gangrene, burrow extensively among the surrounding tissues, be complicated with serious disease of the bones, or, lastly, be indolent and indisposed to heal.

Syphilitic *abscess* of the bones is uncommon.   It may occur in almost any portion of the skeleton, and is characterized by long-continued pain, usually deep-seated, circumscribed, and of a dull, heavy, gnawing character, liable to serious aggravation from

exposure, fatigue, or any disorder of the general health. The diagnosis is determined by the history of the case, by the enlargement of the affected bone, and by the peculiar obstinacy of the pain. When the disease is chronic it may persist for an almost indefinite period, as in the case of a man, thirty-three years of age, a patient of mine, who had a deep-seated abscess of this kind in the upper extremity of the tibia for upwards of nine years. In another case the disease had been in progress for sixteen years.

Caries is most common in the long bones of the extremities, as the tibia and ulna, in the skull, and in the palate, maxillary, nasal, turbinated, and ethmoid bones, together with the vomer; it may exist by itself, or be conjoined with *necrosis*, whole pieces often dying and sloughing away, so as to cause the most frightful mutilation and disfigurement. These ravages are generally most conspicuous about the countenance, especially when the disease attacks and destroys the proper bones of the nose, which then cave in, and cause that remarkable flattening of the face so characteristic of the effects of tertiary syphilis. In many cases the turbinated bones, the ethmoid, and vomer are separated, so as to convert the nasal fossæ into one immense cavity; and instances occur where, from the destruction of the palate and maxillary bones, the mouth and nose communicate with each other. In the long bones of the extremities, the caries and necrosis are generally superficial, the dead portions coming away in the form of exfoliations, the central parts of these pieces seldom participating in the morbid action to an extent sufficient to cause their destruction. The sequester in syphilitic necrosis is characterized by its peculiar

Fig. 85.

Syphilitic Caries of the Skull.

porous, cribriform or worm-eaten appearance, dependent upon the peculiar arrangement of the gummy matter that accompanies the process of osteomyelitis. The cicatrice which is left by the healing of the parts is remarkably hard, compact, poorly supplied with vessels, depressed, and of a uniform, whitish appearance.

Virchow has described what he calls "dry caries" of the osseous tissue, as an effect of syphilis; it is most common in the bones of the skull, and is characterized by the entire absence of suppuration, conjoined with rarefaction of the affected part and hypertrophy of the adjacent textures. It may affect both tables of the skull, and, when the depressions accompanying it correspond, it may cause complete perforation.

The adjoining cut, fig. 85, from Druitt, affords a graphic illustration of caries of the bones of the skull, which, as in a case under my observation many years ago, are sometimes so completely riddled as to give them a peculiar cribriform appearance.

Syphilitic *hypertrophy* of the osseous tissue is extremely common, and sometimes involves the greater number of pieces of the skeleton; the bones, however, which are most liable to be attacked are the tibia, fibula, femur, ulna, radius, and cranium. The lesion occurs either as an exostosis, or as a diffused swelling, which, when it affects the whole length and thickness of a bone, assumes the name of general hypertrophy. The mode of formation of a syphilitic exostosis presents nothing peculiar; it evidently takes its rise in a deposit of plasma, which serves as a nidus for the future growth, the ossific process passing through the same phases as in the natural skeleton. The tumor is usually knobby and irregular, with a broad base, and a rough, scabrous surface. In cases of long standing, it is nearly always of a hard, ivory consistence.

The more common variety of hypertrophy is the diffused or general, of which the best specimens are usually seen in the bones of the leg, thigh, and forearm, which are often nearly twice the natural thickness and of extraordinary weight and firmness. A section of such a piece, seen in fig. 86, from a preparation in my cabinet, shows that the spongy substance has been completely, or almost completely, replaced by solid osseous matter, that the medullary canal has been obliterated, and that the compact structure has acquired a closeness of texture almost equal to that of ivory. The Haversian canals are for the most part obliterated, or greatly changed in size and shape, while the outer surface of the bone, as sketched in fig. 87, is remarkable for its roughness, its appearance bearing a

striking resemblance to that of worm-eaten bark. The skulls of persons laboring under tertiary syphilis are sometimes astonishingly hypertrophied. In a specimen presented to

Fig. 86.

General Syphilitic Hypertrophy of the Femur ; Internal Structure.

me by Dr. Cochran, of Louisiana, the cranial bones are throughout at least half an inch in thickness ; the different pieces are completely fused together without any trace of suture or of diploë, and their consistence and density are almost equal to those of ivory.

Fig. 87.

General Syphilitic Hypertrophy ; External Characters.

Syphilitic *osteophytes* occur, both in the long and the flat bones, in various forms ; sometimes as thin, sharp, thorn-like excrescences, and, at other times, as flat, irregular, triangular, or knobby prominences. They are apparently composed of the same material as the bones from which they spring, and often exist in great numbers, especially in the neighborhood of the larger joints.

Extreme *fragility* of the osseous tissue sometimes arises from the effects of the syphilitic poison. A young man, a patient of mine, fractured his humerus, near its middle, in the act of throwing a chip at a person. He was in feeble health at the time, but, under the influence of tonics and iodide of potassium, union occurred within the usual limits.

The *periosteum* is variously affected in syphilitic diseases of the bones ; in the more inflammatory lesions it is generally very vascular, soft, and spongy, at the same time that it is considerably thickened, and easily detached from the subjacent surface. In hypertrophy, especially the diffused form, the principal alterations are thickening and induration, with a tendency, here and there, to ossification. Instead of being easily separated from the affected bone, as it is in the more acute affections, the membrane always adheres to it with extraordinary firmness.

The various syphilitic affections of the bones, but especially diffused hypertrophy, are all attended with more or less disturbance of the general health, and deep-seated, excruciating pains. These pains, from being always worse at night, have earned for themselves the title of *nocturnal*, although they are rarely entirely absent even in the day ; they are also frequently called osteocopic pains, and syphilitic rheumatic pains. They are generally of a dull, heavy, aching, or gnawing character, and begin to increase in severity the moment the patient becomes warm in bed : they may continue all night, or go off in a few hours, but while they last the patient is in great suffering, and is unable to sleep. Not unfrequently they are of a neuralgic nature, excessively keen, darting, and paroxysmal. While they exist, the affected bones are generally exquisitely tender and intolerant of manipulation.

Joints.—A mild form of synovitis is by no means uncommon in tertiary syphilis, especially in persons of a dilapidated constitution, ill-clothed, and ill-fed. The attack generally comes on stealthily, and may last almost for an indefinite period. The joints most liable to suffer are the knees, elbows, and wrists, though hardly any are entirely exempt from it. The accompanying pain is usually of a dull, aching character, and is always aggravated at night and in wet weather. The affected parts feel sore and tender, and are intolerant of the slightest motion and pressure. The synovial membrane generally becomes thickened and incrusted with gummy matter, while its cavity is partially filled with a

turbid, viscid fluid, sometimes spontaneously coagulable. This fluid, which seldom exists in any considerable quantity, occasionally temporarily disappears, and then recurs from the slightest causes, now perhaps more rapidly and abundantly than in the first instance. The structures around the diseased joint are stiff and indurated from plastic deposits, but the integuments are free from disease. The general health is usually more or less deranged.

In the more severe forms of syphilitic synovitis, the disease extends not only to the articular cartilages, but also to the extremities of the bones; the pain and general disturbance are excessive; the swelling and effusion are great; and the morbid action either ends in permanent anchylosis, or in destructive suppuration and ulceration of the joint.

The diagnosis is determined by the history of the case, by the insidious character of the attack, by the peculiarity of the concomitant pain, and by the coexistence of syphilis in other parts of the body.

3. TREATMENT.

The treatment of tertiary syphilis reposes upon broad, scientific, and philosophical principles, and may, therefore, generally be pursued with a positive certainty of affording great relief, if not ultimate eradication. Even the worst cases may usually be immensely benefited in a very short time under the modern system of treatment; and I have repeatedly seen patients, apparently on the verge of the grave, who had not enjoyed a comfortable night's sleep for years, and whose bodies had been sadly deformed and racked by pains, raised to health and usefulness by a few doses of medicine. The remedy to which we are indebted for these wonderful effects is the iodide of potassium, first employed in this class of affections by Dr. Wallace, of Dublin, a remedy, which, if there be such a thing as a specific, is unquestionably entitled to that distinction. Experience has shown that it exercises the same happy influence in tertiary syphilis as quinine in intermittent fever, or arsenic in neuralgia. It is the remedy *par excellence* in tertiary syphilis; a modern discovery of stupendous consequence to the human race; a remedy without which it would be impossible to treat this disease with any prospect whatever of success in almost any case, however simple. Nevertheless, it must not be supposed that iodide of potassium is absolutely infallible; like quinine and other agents, it occasionally disappoints expectation; but we may safely claim for it a degree of certainty which no other article of the materia medica, except, perhaps, iodide of sodium or iodide of ammonium, possesses as an antisyphilitic in the tertiary stage of the affection.

The exhibition of iodide of potassium may usually be commenced without any preliminary treatment; it is only when the patient is anemic, or when there is great disorder of the secretions that any preparation of the system will be necessary, and then it need generally not extend beyond a few days. The proper mode of exhibition is that of solution in distilled water, either alone, or with some bitter infusion or tincture, as hop, gentian, or quassia, such a combination being particularly desirable when a gentle tonic is required. The dose of potassium has been a prolific source of dispute. Long experience has taught me that, while less than eight or ten grains rarely do much good, there are few cases in which more than this quantity is rarely ever needed, repeated three times a day, at intervals of eight hours, the most favorable period for the administration being about one hour after eating. When a rapid effect is required, as when there is unusual urgency of the symptoms, an additional dose may be given, but this will seldom be necessary. I have occasionally exhibited twenty, twenty-five, and even thirty grains at a dose thrice daily, but the effect, instead of being gratifying, has generally disappointed me, the medicine seemingly acting as an irritant rather than as a calmative, as it does when it agrees perfectly with the system. I have never given the article in drachm doses, as it sometimes is by others, and I should regard such practice as altogether unmeaning, if not positively prejudicial. The disease cannot be taken by storm; the treatment must be chronic, in conformity with the course of the malady which it is intended to cure; hence it requires patience, regularity, and perseverance, rather than a display of vigor and heroism. The object should be to accomplish a certain amount of good every day, until the implacable foe is effectually expelled from the system. If the treatment be conducted upon this plan, a most rapid and decided amendment generally occurs; the sleep, appetite, and strength steadily improve; the countenance loses its wan, cachectic appearance; and in less than a fortnight, often indeed in less than a week, the patient looks and acts as if he were a new being, his whole condition, physical and mental, evincing the astonishing change wrought by the medicine.

Iodide of potassium, especially if given in large doses, occasionally signally disagrees

with the system, rendering it necessary either to suspend its use altogether, or to administer it in a modified form, or in smaller quantity. The most common effects of it are an irritable condition of the air-passages, with a sense of fulness in the head and frontal sinuses, a thin, watery discharge from the nose, more or less sneezing, vascular injection of the conjunctiva, and a general feeling of discomfort, the symptoms strongly resembling those of a severe coryza. These effects sometimes declare themselves after the exhibition of a few doses only of the medicine; at other times they do not appear until after the lapse of eight or ten days, or until the system has been pretty well saturated with it. In some cases, depending evidently upon a strong idiosyncrasy, almost the smallest quantity is sufficient to produce excessive discomfort, and an invincible repugnance to the further use of the remedy. Among the more uncommon effects to which the iodide of potassium may give rise are, gastric irritation, diarrhœa, salivation, glossitis, vesicular eruptions of the skin, excessive diuresis, hemorrhagic discharges from the urethra and vagina, and cerebral excitement not unlike that occasioned by alcoholic stimulants.

The best mode of counteracting these disagreeable effects is to combine with each dose of the medicine an anodyne, as a small quantity of morphia, or a few drops of acetated tincture of opium. In some cases I have found the free use of strong hop tea to answer the purpose, while in others a mere diminution of the dose was sufficient. I remember but few instances in which I was compelled, on this account, to abandon the exhibition of the article altogether.

The length of time during which the potassium should be continued must, of course, vary in different cases and under different circumstances. In the great majority of instances it should be exhibited for many weeks and even for a number of months, with an occasional intermission of three or four days, in order to afford the system a short respite, which is always found to be highly beneficial whenever a medicine is employed chronically. An invariable rule with me is to continue the remedy for several weeks after all disease has apparently vanished; and afterwards to give it for eight or ten days at a time at intervals of a month, on the same principle that quinine is administered periodically for the radical cure of intermittent fever.

Iodide of potassium is sometimes advantageously combined with carbonate or muriate of ammonium, the two articles being given in solution, in equal proportions, thrice a day. As a substitute for this article, I often prescribe iodide of sodium or iodide of ammonium. Both preparations are, I am satisfied, fully equal, as antisyphilitics, to the iodide of potassium. During my connection with the Philadelphia Hospital ample opportunity was afforded me of testing their efficacy in numerous instances of tertiary syphilis in all parts of the body; and for the last fifteen years I have rarely employed anything else in private practice for the relief of this disease. The iodide of sodium is preferable to the iodide of ammonium, as the latter is not only offensive to the taste, but liable, unless combined with some corrigent, to nauseate. The average dose of either should not exceed eight or ten grains, and the best time for their administration is from half an hour to an hour after meals. Their action should be aided, when there is much emaciation, by cod-liver oil, iodide of iron, a generous diet, and alcoholic stimulants.

How the iodides act in affording relief in the treatment of tertiary syphilis, whether by neutralizing the poison, or by eliminating it from the system through the emunctories, is still a mooted question. One thing is very certain, and that is, that it passes off largely by the kidneys, generally within a very short time after it is swallowed.

Although iodide of potassium and its kindred articles alone will often rapidly relieve tertiary syphilis, their efficacy is generally very materially enhanced by the addition of a small quantity of *mercury*. Indeed, so thoroughly am I convinced of the decided superiority of this course, that I have for many years almost invariably employed it, thus greatly abridging the treatment, and much more completely eradicating the disease. The plan is particularly beneficial when the affection is of long standing, when it has deeply penetrated the system, as shown by the existence of nodes, nocturnal pains, and ulcers of the skin, and when the patient has been fruitlessly subjected to frequent courses of the iodides alone. An infirm, broken state of the system is no bar to the use of mercury in this mode of combination; on the contrary, it often affords the medicine an opportunity for its best display, especially if it be used along with tincture of chloride of iron.

The form of mercury which I prefer is the bichloride; it is readily dissolved by the potassium, sodium, or ammonium, and may be given in doses varying from the eighth to the sixteenth of a grain, three times a day. The best plan usually is to begin with the tenth of a grain, gradually increasing the quantity if necessary, on account of the obstinacy of the case, to the eighth or sixth of a grain, which should rarely, if ever, be exceeded. The

effects of the remedy are, of course, carefully watched, the slightest tendency to ptyalism being a sign for its suspension, or, at all events, its more guarded use. It will generally be found beneficial to continue the mineral until there is slight tenderness of the gums, with a metallic taste in the mouth, and to keep up this action afterwards for several weeks by repeating the dose occasionally as the effects begin to flag. In short, chronic mercurialization is aimed at, not acute, which never fails to do harm, sometimes immense and irreparable. After the mercurial course has been sufficiently prolonged, the cure may be completed by the use of one of the iodides, now given by itself, perhaps in reduced doses, simply to maintain a slight constitutional impression.

When the bichloride disagrees, which, however, is seldom the case, a good substitute, will be found in the biniodide, which, indeed, sometimes yields better results than the bichloride. The ordinary dose is one-sixteenth of a grain, gradually increased to one-eighth or even one-fourth, thrice a day. The protiodide occasionally answers well, but is more apt to gripe and nauseate. Donovan's solution, a compound of mercury, iodine, and arsenic, is sometimes advantageously exhibited, the dose being from five to eight drops. It often proves serviceable in relieving rheumatic pains and swellings of the bones and periosteum, but it must be given cautiously, as it is very liable to nauseate.

Instead of giving mercury by the mouth, it may sometimes be beneficially administered by the rectum in the form of suppository, consisting of half a drachm of strong mercurial ointment, rendered stiff with a little tallow, and repeated twice or thrice in the twenty-four hours, until the gums are slightly affected, as they often will be in a very few days. The bowels should be well cleared out previously, after which a little morphia should occasionally be exhibited in order to secure the retention of the suppository. This method of treatment is particularly applicable to constitutional syphilis, as it is at once efficient and harmless.

The hypodermic use of bichloride of mercury, in quantities varying from the eighth to the fourth of a grain every twenty-four hours, has been warmly advocated during the last ten years, especially by Max-Van-Moss, Lewin, Kohn, Müller, and Dr. R. W. Taylor. The chief objections to it are that it is inconvenient, that it is liable to produce abscesses and severe salivation, and that patients are often unwilling to submit to it on account of the pain caused by the prick of the syringe, and the contact of the salt with the tissues. To moderate this, the salt should be combined with the eighth or tenth of a grain of morphia. The most eligible points for the injection are the outer sides of the extremities, the chest, shoulders, loins, and nates. Slight ptyalism usually supervenes in a few days. With a view of overcoming its irritating effects, the remedy may be combined with peptone, by rubbing together one drachm of the bichloride, two drachms of chloride of sodium, and one drachm of peptone, dissolving the product in the smallest possible quantity of water, filtering the solution, and evaporating it in vacuo. When perfectly dry, the mercuric peptone is again reduced to powder, and one drachm to three ounces of distilled water forms a one-per-cent. solution of the corrosive sublimate, of which about twelve minims may be used at each injection. The full value of this species of medication remains to be tested.

When the system is much dilapidated, mercurialization is best attained by inunction, fumigation, or the vapor bath, the remedy, when thus introduced, acting often much more beneficially and kindly than when administered by the mouth, which, indeed, it rarely, if ever, should be in such a condition.

The topical application of mercury is particularly to be commended when the syphilitic disease is of unusually long standing; when the surface is covered with irritable, painful, and intractable sores; when there is deep involvement of the bones, as declared by the existence of nodes, diffused swellings, or caries and necrosis; or when the system is greatly exhausted by protracted suffering, want, and exposure, or long and injudicious courses of mercury by the mouth. Thus employed, its effects frequently display themselves in the most striking and efficient manner, in the rapid and extraordinary improvement that follows in the character of the several local affections and the condition of the general system.

The article commonly employed for *inunction* is the mild mercurial ointment, from a drachm to a drachm and a half being rubbed upon the inside of the thighs and arms, once a day, until the constitutional effects of the medicine become apparent by the state of the gums, breath, and saliva. I usually add a small quantity of powdered camphor, with a view of rendering the ointment more soluble, and thereby facilitating its introduction into the skin. The friction should be very thorough, and continued until the ointment has nearly disappeared from the surface. A more cleanly mode of inunction is to

rub the ointment into the soles of the feet, the action of the remedy being greatly promoted by walking. The same stockings should be worn continuously for a week, when the feet are thoroughly washed with hot water and soap, and the frictions are resumed after an intermission of two or three days. The mercurial ointment may be replaced by the twenty-per-cent. oleate of mercury, diluted with an equal quantity of cosmoline.

Mercurial *fumigations* may be conducted in a very cheap and simple manner. All that is necessary is a large comfort, long enough to extend from the floor to the patient's neck, to which it is carefully secured with a piece of tape, to prevent the fumes from escaping into the room and injuriously entering the sufferer's lungs. Or, instead of this, the body may be surrounded with a cloak of oil- or gum-cloth. The patient, completely stripped, is seated in a large arm-chair, or upon a stool, beneath which is placed the fumigating apparatus, consisting of a tin framework with a thin iron plate, and a small spirit

Fig. 88.

lamp, so situated as not to endanger the safety of the person. The most suitable mercurial preparations are the protiodide, bichloride, and biniodide, as they admit of ready volatilization at a comparatively low temperature, and furnish an abundant vapor. The operation, repeated once a day, lasts from ten to twenty minutes, at the end of which the patient is put to bed, well covered, in order to maintain perspiration. Great prostration, however, may follow this sweating process, if it be carried too far, or renewed too frequently. The duration of the treatment must depend upon circumstances, the average period being from two to three weeks.

Mercurial fumigation may sometimes be advantageously combined with steam in the form of the mercurial *vapor-bath*. A very simple mode of applying it is to volatilize the mercury, and to convey the steam by means of a tube from a boiler to the patient's body as he sits in his chair. The most unexceptionable plan, however, is the employment of a tin vessel, with two compartments on the top, one containing a pint of hot water, and the other, the central one,

Maury's Fumigating Apparatus.

the requisite quantity of mercury. The heat is applied with a spirit lamp, the patient being wrapped up in the usual manner. Instead of this contrivance, the more elaborate apparatus represented in fig. 88, and devised by the late Dr. Thomas F. Maury, of Washington, which may be attached by means of a flexible tube to an ordinary gas fixture, may be employed. The best articles are the protiodide, bichloride, and biniodide of mercury, their volatility, as I have ascertained by experiment, being in the order here enumerated. Calomel requires a much higher temperature for volatilization than these preparations, while the red sulphuret, formerly so much employed, is altogether unfit for the purpose. Whatever substance be used, the vapor should be brought as thoroughly as possible in contact with the syphilitic sores.

More or less of the mercury is usually deposited upon the surface of the body, where it must be left to undergo partial absorption. Hence special care must be taken not to wipe the skin. A little vapor, freely diluted with air, may also be inhaled, especially if the principal disease is in the nose and mouth. The operation should be repeated once a day, from ten to twenty minutes at a time, when the patient is put to bed, well covered, to favor gentle perspiration.

When there is much disorder of the secretions, derangement of the alimentary canal, or a feverish state of the system, a short course of preliminary treatment will generally be necessary, as this will greatly augment the efficacy of the fumigation.

Simple and medicated *baths* often prove serviceable in tertiary syphilis, not only as means of cleanliness, but by the direct soothing and healing influence which they exert

upon the part and system. They are particularly beneficial in ulcers of the skin and in rheumatic pains of the bones and joints. An emollient bath, prepared with starch or wheat bran, generally proves most grateful. The common salt-water bath, or a bath containing a small quantity of carbonate of potassium or chlorinated sodium, is an excellent detergent and stimulant in the foul ulcers of the skin and bones so common in the advanced stages of syphilis. Occasionally the water may be advantageously impregnated with bichloride of mercury, from three to ten grains of the salt being added to the gallon of fluid, and the immersion continued for twenty, twenty-five, or thirty minutes. Much caution, however, is required, especially when the surface is considerably denuded, otherwise severe ptyalism may arise. Baths containing nitric, hydrochloric, carbolic, or acetic acid, are sometimes beneficial.

Besides mercury and the other articles above mentioned, there are certain remedies which, although usually considered as being merely auxiliary, are, nevertheless, of great consequence in a curative point of view in the treatment of syphilis. At the head of these may be placed a properly regulated diet, tonics, sudorifics, and anodynes, which deserve the greatest attention in every case of the disease.

It is impossible to insist too strongly upon a well-regulated *diet* in the treatment of this affection, when it is recollected how much its progress and virulence are influenced by the exhausted and impoverished condition of the system which so generally attends it in its more advanced stages. No medicine can possibly produce its full effects under such circumstances, without the aid of good, wholesome, and easily digestible food, stimulating drinks, especially brandy or whiskey, and an abundance of milk and fresh air. The blood must be enriched and the solids rebuilt before it will be possible to neutralize the specific virus, or to eliminate it from the system.

Tonics are nearly always indicated ; and quinine and iron usually answer better than any other combination. The bitter extracts, as gentian and quassia, are generally useless, except in so far as they may tend to improve the appetite. Occasionally benefit accrues from the use of some of the mineral acids, particularly the nitric and phosphoric, largely diluted with water. Formerly, powerful antisyphilitic properties were ascribed to these articles, but it is probable that their good effects are solely due to their tonic virtues, and not to any agency in neutralizing the syphilitic poison. When much emaciation exists, with want of assimilative power, or a feeble digestion, there is no more useful article than cod-liver oil, given in doses suited to the state of the stomach and the general condition of the system.

Sudorifics have long held a high rank in the treatment of syphilitic affections, under a supposition that they aid in eliminating the venereal poison, thus ridding the system of its noxious influence. Whether they possess such property or not, there is no question as to their general usefulness in all states of the economy attended with obstructed perspiration, so often present in the advanced stages of syphilis, particularly when there is serious involvement of the skin. The object for which such medicines are usually prescribed may readily be obtained by the warm, hot, or steam bath, assisted by tepid drinks, and various kinds of diaphoretics, as Dover's powder, antimony and morphia, and similar articles. Some caution is necessary in the use of sudorifics, lest injurious debility be induced.

But of all the auxiliary remedies now described, the most important, in every respect, are *anodynes;* their employment is absolutely indispensable, and it is, therefore, impossible to assign to them too high a rank. They are, up to a certain stage of the treatment, of more consequence even than food and drink. The patient is not only unable to sleep, but his body is literally racked with pain and irritability. To look, under such circumstances, for any substantial improvement from ordinary remedies, would simply be absurd. The first thing to be done is to quiet the system and induce sleep ; and to accomplish this, anodynes must be exhibited in large and sustained doses, a quarter of a grain of morphia, or its equivalent of solid opium, laudanum, or black drop, being given every eight, ten, or twelve hours, according to the effects of the article. The manner in which anodynes are often borne, in the worst forms of tertiary syphilis, is astonishing, and can only be explained by the tolerance established by the irritable condition of the nervous system. When the insomnia depends upon exhaustion, the morphia may generally be advantageously combined with chloral, or chloral may be freely given by itself.

As to *sarsaparilla*, formerly so much vaunted in the treatment of this disease its employment in my hands has never been productive of any appreciable benefit. Whether this has arisen from ill luck, or from the use of an inferior article, it is not in my power to affirm ; I may state, however, that I have exhibited it in every form and mode of

combination in which it is given in this and other countries, and am, therefore, inclined to believe that it has been invested with virtues which do not belong to it, or which are due mainly, if not solely, to its associate ingredients.

Finally, persons laboring under tertiary syphilis should have the benefit of a pure, dry atmosphere, and be well protected from cold by flannel worn next to the skin both summer and winter. When it is remembered how easily the disease is provoked by suppression of the cutaneous perspiration, and by living in damp, underground, and ill-ventilated apartments, the importance of attention to this injunction cannot fail to be fully appreciated.

Sea bathing and a residence at the seaside are often of advantage in syphilitic persons of deteriorated constitution; and the Hot Springs of Arkansas have become a sort of El Dorado for this class of patients, thousands annually flocking to them from different sections of the United States. It is questionable, however, whether the use of these waters is of any real benefit. The good which results from the visits is probably due, in great measure, if not entirely to the change of air, food, and scene, and to the liberal employment of the iodides and of mercury to which this class of patients are invariably subjected by the resident physicians. The use of sulphur water, in the form of drink and baths, has also been greatly extolled, but the praises lavished upon it have never been realized. In France, Germany, and other European countries there are a number of resorts celebrated for their supposed antisyphilitic virtues.

Syphilitic affections of the nervous system must be treated with the iodides in very large doses, experience having shown that the doses administered in syphilis as it occurs in other parts of the body are worse than useless. Not less than twenty, twenty-five, or thirty grains should be given thrice a day an hour and a half after meals, and this quantity should be gradually increased, with an occasional intermission, to the full extent of tolerance of the stomach. The efficacy of the prescription will be materially increased by the addition to each dose of the eighth or tenth of a grain of bichloride of mercury and an occasional large dose of quinine. An issue made with the hot iron when the seat of the disease can be localized, will be found to be a powerful adjuvant. When, from idiosyncrasy, or any other cause, the iodides are inadmissible, our main reliance must be upon mercury, carried, if the system is not too much impaired, to slight but persistent ptyalism.

The treatment of tertiary syphilis of the heart and bloodvessels, the lungs, liver, and spleen, differs in no respect from those just mentioned in connection with the treatment of syphilitic affections of the nervous system. The great point is to push the remedies to the utmost before the gummy or specific matter has undergone the softening process.

In regard to the topical treatment there are certain rules which are applicable to all local affections, whatever their nature, site, or extent. Thus, there can be no hesitation about the removal of dead bone, opening abscesses, tracing out sinuses, dividing fasciæ or aponeuroses, and trimming off the ragged, undermined, and impoverished edges of cutaneous ulcers, so as to place them in a more suitable condition for speedy repair. All this is self-evident, and only requires mention to secure attention. Cleanliness is of paramount importance, as it contributes not merely to personal comfort, but also, in a powerful degree, to recovery. Fetor is allayed by the free use of deodorizers, as chlorinated sodium and permanganate of potassium.

Ulcers, fissures, eruptions, papules, and tubercles of the *skin* often recover under very simple topical treatment, as weak solutions of nitrate of silver, or acid nitrate of mercury, aided by the use of iodide of potassium, or potassium and mercury, with attention to cleanliness and other hygienic observances. When much inflammation is present, with a foul appearance of the part and a tendency to spread, acetate of lead and opium will come in play, with emollient cataplasms, or warm water-dressing, simple or medicated. Touching the sores lightly once a day, or every other day, with dilute acid nitrate of mercury or a weak solution of nitrate of silver, generally singularly promotes the cure. Unguents are not always as bad as they have been represented to be in these cases. I have often employed them with excellent effect, especially opiate cerate, balsam of Peru ointment, and ointment of nitrate of mercury, weakened with six, eight, or ten times its bulk of simple cerate or cosmoline. Mercurial ointment, diluted, and mixed with opium, frequently makes a most useful dressing in the indolent form of rupial ulcer. Sprinkling the surface of the sore with calomel, iodoform, or nitrate of lead, and keeping it covered with dry lint, sometimes rapidly promotes cicatrization.

The bronze and copper-colored stains of the skin which follow certain forms of syphilis are often very unseemly, and, therefore, a source of annoyance to the patient. The best remedies are minute doses of mercury and the frequent use of the sulphur vapor-bath.

Syphilitic *onychia* is, strictly speaking, a rupial ulcer, to be treated in the same manner as similar sores elsewhere. One of the most valuable applications is nitrate of lead, sprinkled upon the sore several times a day, and kept in place with dry lint. Iodoform is also a useful remedy. Unhealthy granulations must be repressed with caustics or the scissors. If abscesses form under the nail, they must be punctured; and if the nail die, it must be removed, or trimmed, especially if it overhang and injuriously compress the diseased structures. Friable onychia demands no special treatment beyond trimming of the nails, and the application of lead water, if the soft parts around are inflamed.

The topical treatment of tertiary ulcers of the *throat*, mouth, and tongue is restricted principally to applications of acid nitrate of mercury and solid nitrate of silver, at first once a day, and subsequently every third or fourth day, according to the condition and progress of the sore. Weak gargles, or washes of acetic acid, tannic acid, and sulphate of copper, chlorinated sodium, or cyanuret of mercury, from ten to sixteen grains of the salt to a pint of some bland, mucilaginous fluid, as linseed tea or infusion of elm bark, may be employed in the intervals.

In the treatment of syphilis of the *nose*, the chief reliance must be upon injections of weak lotions of iodide of iron, sulphate of copper, and tannic acid, tincture of myrrh, permanganate of potassium, and chloride of zinc, particularly the latter, as they impart not only a healthy stimulus to the affected surfaces, but effectually allay fetor, so distressing in this class of complaints. Mercurial preparations are generally improper, from their liability to pass into the stomach, and thus occasion salivation. In using injections for the nose, a large syringe with a long, perforated nozzle is required, to bring the fluid fully in contact with every portion of diseased structure. They should be repeated at least thrice a day, with special care not to distress by their severity. The hydrostatic mode of cleansing and medicating the nose, with Thudichum's apparatus, is now generally, and, indeed, very justly preferred to the more ordinary procedure, as it is far more thorough and effective.

If the affected parts are within reach, regular and steady medication may be effected with lint smeared with some suitable ointment, as glycerine and tannic acid, or wet with some slightly stimulating lotion, as Goulard's extract, nitrate of silver, sulphate of copper, or chlorinated sodium. In all cases the nasal cavities should be frequently inspected, with a view to the early detection and removal of dead bone.

In syphilis of the *larynx* direct medication may be attempted by means of the mop wet with a weak solution—from ten to twenty grains to the ounce—of nitrate of silver, introduced once every third or fourth day, the patient being at the moment partially under the influence of chloroform, so as to render the parts more passive, and, consequently, more tolerant of the operation, which is otherwise very apt to prove abortive. When the disease is extensive or the case urgent, as when there is deep ulceration with excessive difficulty of deglutition, frequent spasm of the muscles, or œdema of the glottis, the only resource is tracheotomy. Direct medication may then be made with acid nitrate of mercury or with any other article that may seem expedient. If warty excrescences exist, they may be clipped off with the scissors, repullulation being prevented by escharotics or sorbefacients. Dead cartilage is removed in the usual way.

The great remedy for syphilitic *iritis* is mercury pushed to rapid but general ptyalism. If the patient is young or plethoric, blood is freely taken from the arm, or by leeches and cups from the temple. Opium is given to allay pain and to restrain the action of the mercury upon the bowels. If, on the other hand, there is evidence of exhaustion, or of an anemic, shattered state of the constitution, stimulants and tonics, as iron and quinine, with a generous diet, and gentle exercise in the open air are at once employed. Mercury is either entirely omitted, or administered very sparingly. In general, the most suitable article, in this condition of the system, is corrosive sublimate in union with iodide of potassium. Turpentine, so strongly recommended by Carmichael and others in such cases, as a substitute for mercury, is seldom of any use, and is certaidly not reliable as a curative agent. In addition to these general measures it is of the first importance to keep the pupil constantly dilated by instillations of four grains of sulphate of atropia to the ounce of distilled water.

Syphilitic ulcers of the *eyelids* generally promptly yield under the influence of iodide of potassium and the application of very dilute citrine ointment.

Syphilis of the *ear* is managed upon the same general principles as syphilis of other organs. The great remedies are mercury and potassium, aided by leeches, blisters, and mildly astringent injections.

The local treatment of affections of the *bones* and periosteum must be strictly anti-phlogistic. The pain and swelling are often immensely benefited by tincture of iodine, leeches, and blisters, although in very many instances they readily yield to the exhibition of iodide of potassium and mercury. A node, as a rule, should not be opened so long as it is very small, and free from serious annoyance; when the reverse is the case, it should be freely incised, and so also if it be the seat of distinct fluctuation, denotive of the exist-ence of matter. A good rule, under such circumstances, is to make the knife graze the bone, imperfect division of the parts being generally worse than useless. If the resulting ulcer is slow in healing, it should be well blistered, or dressed with mercurial ointment, or some stimulating and anodyne lotion. Sometimes the pain and tension of a node may speedily be relieved by subcutaneous incision, effected by means of a delicate bistoury, carried about in different directions and in such a manner as also to divide the periosteum. Necrosed bone must be removed as soon as it is sufficiently loose to admit of easy separa-tion; while carious bone must be scraped and otherwise managed to put it in a suitable condition for repair. Diffused hypertrophy rarely requires any other than constitutional remedies. When the affection is circumscribed or not too widely extended, great and prompt relief sometimes follows the use of the trephine, several small, circular disks being removed by carrying the instrument nearly through the entire thickness of the affected bone. When the disease is caused by an abscess, nothing short of such an operation will be of the slightest benefit. Evacuation must be effected without delay. An exostosis, acting obstructingly, must be removed with the saw or pliers.

The most suitable means in syphilitic *synovitis* are iodide of potassium and mercury internally, and locally acetate of lead and opium, leeches, blisters, and tincure of iodide, with perfect rest of the affected joint.

Syphilitic *sarcocele* is treated, topically, upon the same principles as swelling of the testicle from gonorrhœa; by rest of the body and elevation of the parts, leeches, astringent and anodyne fomentations, and mild mercurial inunctions. When the enlargement is indolent and rebellious, strapping may be employed, either with common adhesive plaster, mercurial and ammoniac plaster, or the plaster of Vigo. The cure is often retarded in these cases by the presence of a considerable quantity of serum in the vaginal tunic, com-pressing and irritating the diseased organ; an effect generally promptly relieved by a free incision, or by numerous punctures. Abscesses are treated in the ordinary manner. Internally free use is made of the iodides.

When the testicle is fungous, ulcerated, and completely disorganized, the only resource is removal, no treatment, either general or local, proving of any service in such a case. Before, however, so serious an operation is ventured upon, it should always be ascertained by exploratory incisions that the organ is really, and not merely apparently, past recovery.

The treatment of *condylomatous* growths must be general and local. Topical applica-tions alone will, it is true, often effect riddance without difficulty; but to cure the disease permanently constitutional medication is usually indispensable. The most efficacious remedy, undoubtedly, is iodide of potassium in union with bichloride of mercury, admin-istered as in ordinary cases of tertiary syphilis, the diet, bowels, and secretions being at the same time suitably regulated. The specific treatment should be prolonged, in a modi-fied manner, for several weeks after all disease has apparently vanished, in order to break up the tendency to recurrence.

In regard to the topical treatment, cleanliness is of primary importance, hardly less on account of the attendants than the patient himself. Free use must be made of tepid water, impregnated with chlorinated sodium, and applied by means of a sponge or syringe, the dressings and the bedclothes being frequently sprinkled with the solution, especially if there be much discharge. Another important element of treatment is perfect rest with isolation of the affected parts, their contents, as previously stated, having a tendency to foster growth and secretion. To repress the tumors, various articles may be used, one of the best of which is chromic acid, brushed on once in the twenty-four hours, until they are shrivelled and dried up, as they generally will be in a few days. A lotion of bichloride of mercury, in the proportion of twenty grains to the ounce of water, is also an excellent remedy. Nitrate of silver, nitric acid, and acid nitrate of mercury, so commonly recom-mended, are all extremely severe, besides being very uncertain. In the intervals of the applications, the excrescences should occasionally be sprinkled with some desiccating sub-stance, as calomel, prepared chalk, or carbonate of zinc, and protected with a large roll of dry lint, retained with a T-bandage. Under this management, the tubercles soon lose their sensibility, and rapidly disappear. Perfect cleanliness must be observed for a long

time after the cure is completed, otherwise relapse may occur. When unusually large and rebellious, the growth is more easily disposed of with the scissors, the hemorrhage, which is often copious, being repressed, if necessary, with Monsel's salt.

SYPHILIS IN THE INFANT.

There are two modes in which infants may become infected with syphilis. First, they may suffer from direct inoculation, and, secondly, the disease may be communicated by either parent; by the father in the act of copulation, or by the mother during the progress of pregnancy. It has also been supposed that a child may be contaminated by the milk of an unsound nurse ; and there are numerous cases upon record, going to show that the poison may be communicated in suckling by a sore or mucous tubercle on the nipple. Direct primary syphilis, however, is most generally contracted during parturition, as the child passes through the soft parts of the mother, from inoculation of the body with the secretions of a chancre of the uterus, vagina, or vulva. The idea that the specific matter may enter the system through a sound surface, by the agency of the absorbent vessels, is untenable.

In whatever manner the infection is communicated, the disease pursues the same course as when it occurs in the adult, whether from sexual intercourse or artificial inoculation. The child may perish from the local irritation, or, if it survive the primary affection, it may afterwards suffer from constitutional syphilis, the impression manifesting itself in cutaneous eruptions, mucous tubercles, sore throat, ulceration of the nose, gummy tumors in different parts of the body, and rheumatic pains in the bones and joints.

In the great majority of cases of infantile syphilis, however, the disease is communicated either through the seminal fluid of the father in the act of procreation, or by the mother through her blood after the ovum has taken up its residence in the uterus. That the contamination may occur in both of these ways is a fact that has long been incontestably established. The semen is a living fluid, and in a man laboring under constitutional syphilis the probability is that every spermatozoon is completely impregnated with the specific poison; hence it is only necessary that it should come in contact with the ovum of the mother in order to produce thorough vitiation of the new being. Thus, the very fountain of life is poisoned in the very act of conception, and it is, therefore, not surprising that all its sources should participate in the evil thus entailed.

The time at which a female with secondary symptoms may communicate the poison to her offspring cannot be accurately stated. The probability is that it is very short. This is proved by the circumstance that such a woman frequently aborts within a few months after conception, evidently from the deleterious effects of the virus upon the fœtus. It is supposed that syphilis may be communicated to the child through the amniotic fluid, but if this be so, the question is still an open one.

It has been alleged that a healthy child, or child born of healthy parents, may be infected by a nurse affected with secondary syphilis; the milk being tainted, and capable of communicating the disease. Of the possibility of such an occurrence I entertain great doubt; my own practice has certainly not afforded me any examples of it, while it has fallen to my lot to see several cases where the converse was the fact, healthy children having sucked infected women, and yet remained perfectly sound.

As an infected mother may communicate syphilis to her child in the womb, so, on the other hand, may a child, contaminated by its father, impart the disease to the mother, although she may herself have been perfectly sound at the moment of conception. The occurrence, however, is by no means constant. Dr. Victor De Mèric, for example, has collected not less than thirteen cases in which the mother gave birth to a syphilitic child, and yet she herself never exhibited any signs of the malady in her own system.

The question, whether an infected infant can communicate the disease to its nurse in the act of suckling, is well settled. The secretion from a mucous tubercle of the tongue, cheek, or lip may thus be brought in immediate contact with the nipple, which it will be almost sure, eventually, to inoculate, especially if it be the seat of any cracks, fissures, ulcers, or abrasions. It has been alleged, with a good deal of plausibility, that a woman affected in this manner may, in turn, infect her own offspring. In a case related by Mr. Hunter, and upon which great stress has usually been laid by authors, it is asserted that the diseased infant thus successively inoculated three wet-nurses, two of whom afterwards conceived, and were delivered of syphilitic children. Although a wet-nurse may contract the disease in this manner, there is not, so far as is at present known, a reliable instance

upon record in which a mother has ever been infected from suckling her own offspring. This apparent anomaly is readily explained by the fact that when the system has once suffered from a taint of this kind, it is not susceptible of a second attack. It proves the unicity of the poison, and shows that, under such circumstances, either both mother and child are equally affected, or that the mother is from some constitutional inaptitude incapable of contracting the disease.

The question whether a husband laboring under secondary syphilis may communicate the disease to his wife through the agency of the semen, unaccompanied by impregnation, is no longer a mooted one. It is absurd to suppose that this fluid, when injected into the vagina and uterus, is ever absorbed, no matter how long it may be retained, so as to make a prejudicial impression upon her system. Of such an occurrence there is certainly no satisfactory proof. It is different when conception occurs. Here, as already seen, the semen mixes directly with the ovum of the female, to which it at once imparts its deleterious properties, thereby effectually tainting the new being in the very act of its creation.

Hereditary syphilis is generally a grave disease; for, unless it is judiciously treated, it nearly always proves fatal. A great majority of the neglected cases terminate in abortion, the fœtus often perishing as early as the end of the third month, and from thence on death may occur at any period up to the full term of gestation, the child being usually thrown off in a putrid and more or less offensive condition.

The immediate cause of abortion in a syphilitic mother is a diseased state of the placenta, commencing, apparently, at an early stage of pregnancy, in inflammation of the decidua, by which its substance is indurated and thickened, followed by obstruction in the maternal circulation, and consequent atrophy and arrest of development of the fœtus. In addition to this there is always a greatly deteriorated state of the mother's blood, rendering it unfit as a source of nourishment. When the disease is communicated by the father, the placenta generally suffers secondarily, the syphilitic affection beginning in the fœtus.

The number of abortions is sometimes remarkable; in one instance, under my own observation, it amounted to thirteen, the woman never having brought forth a healthy infant; and in another there were fifteen abortions and miscarriages, with two healthy births between the seventh and ninth mishaps. Cases of three or four successive accidents of this kind are by no means uncommon. Now and then a woman will abort several times consecutively, and then be delivered of an apparently healthy child; I say apparently healthy, for, although the new being may be perfectly plump and fat, and exhibit all the outward signs of the most perfect integrity, yet generally, in a very few weeks, it will be found to present unmistakable marks of decay and disease. The first thing that is usually noticed in a syphilitic child is that it loses flesh and strength, becoming gradually thin and puling, and looking as if it had been withered by the sudden drying up of its juices. The skin, of a dingy, muddy shrivelled appearance, hangs about in loose, soft folds. The countenance, shrunken, wan, and ghastly, resembles that of a man of seventy-five or eighty, instead of an infant a few weeks old. The voice is husky; the respiration is snuffling; the throat is sore; the gums are red and spongy; the lips and anus are fissured; and the body is covered with copper-colored eruptions, usually of the scaly kind, and intermixed with tubercles. Purulent ophthalmia is not uncommon, the inflammation coming on within two or three days after birth, and generally ending in total blindness. In some cases numerous superficial ulcers are found upon the surface, attended with a thick, tenacious, discharge, and a hard, reddish, characteristic base. The hair often drops off in large quantity, both on the scalp, the eyebrows, and on the rest of the body. The well-developed node and orchitis are of rare occurrence in infantile syphilis. Death, under such circumstances, usually occurs within the first three or four weeks after birth. Occasionally, the patient may reach the end of the second or third year, and in exceptional instances life may even be prolonged until after the period of puberty, the individual having a stunted, sickly growth, accompanied, perhaps, with deep ulcerations of the throat, palate, nose, and skin, disease of the teeth, especially of the upper central incisors, caries of the bones of the extremities, and stiffness of some of the principal joints. Few children recover, and those who do are doomed to drag out a miserable existence, generally amidst the most loathsome and disgusting deformities.

Under proper treatment, especially the judicious use of mercury, the specific virus in a syphilitic woman, may in time, be so completely neutralized as to enable her to bear healthy children. Bumstead thinks that, as a rule, after the lapse of six years, the influence of the disease is so far exhausted as to render the risk of transmission very slight. Such a statement must have many exceptions.

Infantile syphilitic eruptions are liable to be mistaken for some of the more common

affections of the skin incident to early childhood, and the diagnosis is, therefore, not un-frequently environed with great difficulty. In obscure cases, the chief reliance is to be placed upon the history of the attack, and other concomitant circumstances. From three to four weeks after birth is the average period of the appearance of the cutaneous affec-tions, the sole of the foot, the buttock, scrotum, face, chest, and inside of the thigh and arm being the parts originally involved. The surface immediately around the eruptions is of a coppery, reddish-brown, or bronze color, a condition very different from what is observed in ordinary diseases, especially eczema, lichen, prurigo, and lepra, with which they are most liable to be confounded. Besides this, which is always a most important symptom, diagnostically considered, the general appearance of the infant shows that it has received a severe shock; it is thin and emaciated, and progressively fails to an extent and in a manner altogether unusual in common cutaneous maladies. The old, withered, and shrivelled look of the child is, of itself, almost characteristic of the disease; the snuffling is another important element in the discrimination of the case, and too much stress cannot be laid upon the mottled, dingy, or muddy state of the skin. The history of the case will usually show that the parents have been the subjects of syphilis, or that they are actually suffering from its effects.

Much stress is very properly laid upon the condition of the teeth as a diagnostic sign in hereditary infantile syphilis, attention having first been directed to the subject by Mr. Hutchinson, of London. The disease occurs chiefly in connection with, or as a result of, specific stomatitis, and displays itself more particularly in the upper incisors, although the lower incisors and even the canine teeth occasionally participate in the morbid action. The first evidence of the disease generally is a dirty, dingy, or light brownish appearance of the enamel of the central and afterwards of the lateral incisors, which soon begin to soften and crumble away, the child ultimately becoming edentulous. Both sets of teeth are cut prematurely, as well as very irregularly, as it respects their position in the jaw; and, unless the constitutional taint is early eradicated, the permanent are doomed to share the same fate as the temporary, although they are destroyed less rapidly.

Mr. Hutchinson considers the upper central incisors as the test teeth of hereditary syphilis. "When first cut," he remarks, "these teeth are uncommonly short, narrow from side to side at their edges, and very thin. After a while a crescentic portion from their edge breaks away, leaving a broad, shallow, vertical notch, which is permanent for some years, but between twenty and thirty usually becomes obliterated by the premature wearing down of the tooth. The two teeth often converge, and sometimes they stand widely apart. In certain instances, in which the notching is either wholly absent or but slightly marked, there is still a peculiar color, and a narrow squareness of form, which are easily recognized by the practised eye." The characteristic appearances of infantile syphilitic teeth are well illustrated in figs. 89 and 90.

Fig. 89.   Fig. 90.
Syphilitic Temporary Teeth.   Syphilitic Permanent Teeth.

The eye also frequently suffers in inherited syphilis, iritis, and corneitis being the affec-tions most commonly met with; they are more frequent in female than in male children, and occur alike in the well-fed and in the half-starved. Iritis seldom appears before the fifth month, and is usually attended with an abundant effusion of lymph, with great danger of occlusion of the pupil. Corneitis is most frequent from the eighth to the fifteenth year, and is almost invariably associated with a dwarfed and notched condition of the perma-nent central incisor teeth of the upper jaw. It generally gives rise to marked opacity of the cornea.

Deafness is a not infrequent result of inherited syphilis. It may come on soon after birth, but it is most common from the tenth to the twentieth year; and, although it is gen-erally accompanied by more or less otorrhœa, it is essentially due to organic changes in the delicate structures of the internal ear; mainly, in all probability, to disease of the

auditory nerves. Inherited syphilis is a fruitful source of deaf-muteism. The loss of hearing nearly always affects both ears.

Ulcers of the tonsils, uvula, palate, and pharynx are not infrequent; they usually come on before the eighth or tenth year, exhibit an excavated appearance, and, if not carefully watched, are apt to produce great havoc in the affected structures. The diagnosis is always easily determined by the peculiar character of the ulcers and their coexistence with syphilitic disease in other parts of the body.

Nodes, enlargement at the junction of the epiphyses with the shafts, hypertrophy, and other affections of the bones of the extremities are very uncommon in infants; but sufficiently frequent in children, especially in the humerus, radius, and ulna, which occasionally suffer simultaneously. Nodes of the phalanges of the fingers—the dactylitis of authors—are sometimes observed. A number of such cases have been under my care at the College Clinic, as well as in private practice. In a few of the cases the affection was congenital. The gummy matter is generally deposited, either simultaneously or successively, in the areolar osseous tissue and between the bone and periosteum, leading to great enlargement and deformity, attended with livid discoloration of the skin, and more or less pain, followed, at length, by suppuration and a bad form of ulcer, often involving several of the phalanges and even the contiguous joints. Nodes in children are occasionally multiple. It is a curious fact that the bones of the lower extremities, which so frequently suffer from syphilis in the adult, are seldom involved in this disease in very young subjects. Marked prominence, with more or less tenderness on percussion, of the frontal protuberance and cranial sutures is often met with, the affected part some-times presenting the appearances of slight exostoses. Syphilitic onychia is most common in very young children.

Inherited syphilitic hypertrophy of the osseous tissue occasionally exists in a remarkable degree, as in a case at the College Clinic, in 1867, in a lad, fourteen years of age, in which the disease was, apparently, entirely limited to the radius, which was enlarged in a most extraordinary degree, both in length and thickness, from one end to the other. The wrist and elbow joints were normal. The right arm had been amputated at the shoulder some months previously, on account of necrosis of the head and shaft of the humerus, attended with destruction of the articular cartilage, and great exhaustion from pain and suppuration. Treatment failed to make any impression upon the hypertrophied bone.

Parrot has recently described an atrophic lesion of the cranial bones in inherited syphilis, in which there is gelatiniform transformation of the osseous tissue. The bones present a worm-eaten appearance, and the metamorphosis begins beneath the periosteum. The change cannot be recognized during life.

The large joints, especially the elbow, knee, and ankle, are liable to suffer during the pro-gress of hereditary syphilis; the attacks are uncommon in early childhood, but are not infre-quent after the fourth year, and are then generally attended with considerable pain, heat, and swelling, attended with more or less effusion of synovial fluid and disorder of the general health. In badly healed or neglected cases, the disease may terminate in abscess, anchylosis, or even complete destruction of the component structures of the affected joints.

Syphilitic periostitis is very uncommon in infants, for the reason that in them all kinds of syphilitic affections are secondary, whereas in children they are tertiary. Nocturnal pains are also of rare occurrence as an effect of inherited syphilis. Syphilis of the testis in infants is uncommon. It is characterized by great hardness of the organ, caused by interstitial hypertrophy of the connective tissue, and is occasionally noticed within a few months after birth, although it is most frequent after the second year.

The gummy tumor of the heart is probably much more frequent in hereditary syphilis than is generally supposed. The disease has been studied with great care by Professor Virchow, who, in 1868 showed me numerous preparations illustrative of its nature and history. The liver also occasionally suffers in a similar manner.

Hemorrhage is an occasional occurrence in hereditary syphilis, manifesting itself at various periods after birth, in some of the numerous outlets, as the mouth, anus, rectum, or vagina; in blotches under the skin, as in purpura; in effusions into the serous sacs; or in deposits in the substance of the brain, lungs, liver, or spleen. I have met with two cases in which fatal hemorrhage proceeded from the stump of the umbilicus of syphilitic children less than ten days old. In whatever form appearing, it is always denotive of a profoundly syphilitic condition of the system, and admits of no relief from treatment.

Affections of the nervous system are not uncommon in inherited syphilis, appearing in various forms, sometimes soon after birth, at other times not until the age of ten, twelve,

or even fifteen years. The most frequent developments are chorea and epilepsy with paralysis of some of the cranial nerves, and affections of the retina, or of this membrane and of the choroid. Hemiplegia, with or without aphasia, is another occasional occurrence. Death in this condition of the system is often sudden and unexpected. Dissection generally reveals the presence of gummy tumors, softened cerebral substance, arterio-capillary constriction, and various albuminoid or protoplasmic nutritive changes.

The development of hereditary syphilis is occasionally postponed until a very late period, as the fifteenth, eighteenth, or twentieth year; and there is reason to believe that the poison may remain latent in the system even for a much longer time. It is an interesting fact that the subjects of hereditary syphilis are either insusceptible of primary syphilis, or, if they contract the malady, that they suffer from it in a modified form.

Finally, hereditary syphilis, by impairing the general health, or, in other words, gradually undermining the powers of life, predisposes to scrofula, rickets, and phthisis. How far it may act as a cause of certain malformations, as harelip, cleft palate, or bifid spine, is still an open question.

Treatment.—The treatment of infantile syphilis is prophylactic and curative. If the mother be suspected to be laboring under a constitutional taint, as she justly may be if she has had several consecutive abortions or miscarriages, or if she is in infirm health, with eruptions upon the skin, a plentiful discharge from the vagina, or an ulcerated condition of the neck of the uterus, she should be promptly put upon a course of mercury and a properly regulated diet, in order to prevent the ill effects of the contaminated state of her blood upon the fœtus, and thus enable the latter to attain its full growth, and the full period of gestation. The mercurial course should be chronic, not acute, and as gentle as possible, lest it should excite abortion; and in most cases it will be beneficial to associate the mineral with the iodide of potassium and some preparation of iron, with a view to a tonic effect upon the general system, which, as already stated, is usually in an impaired and cachectic condition, and, therefore, in need of great attention to raise it to its normal level. The diet should be mild and nutritious, the clothing warm, and the patient well supplied with fresh air.

As soon as the child is born it should be taken from its infected mother, and confided to a sound wet-nurse, as an appropriate diet is absolutely essential to its preservation. If no suitable wet-nurse can be obtained, it should be furnished with an abundant supply of fresh cow's milk, or, what is better, of the milk of the ass, which approaches nearer to human milk, in some of its more important properties, than that of any other animal. The body and limbs should be well protected with flannel, and frequently bathed with tepid water, impregnated with bran, starch, or mucilage, especially if there be eruptions, fissures, or ulcers upon the skin. The child should breathe none but the purest air. The fact is, too much attention cannot be paid to hygienic measures. Cod-liver oil will prove a valuable adjuvant in all cases in which it agrees with the stomach. When the disease is associated with anemia and coldness of the extremities, quinine and iodide of iron must be employed, in combination with brandy, whiskey, or milk punch.

The most important internal remedy is mercury, and it is here that this article often displays its effects to the greatest advantage in neutralizing the specific virus. If any one should be inclined to doubt the efficacy of this medicine, as an antisyphilitic agent, his skepticism will soon vanish if he will take the trouble to watch the progress of the treatment and the good results that will be sure to follow it. If it is not positively a specific, it approaches as nearly to this property in this disease as anything well can, quinine in intermittent fever hardly excepted. The form of exhibition is the bichloride, in doses varying from the fortieth to the fiftieth of a grain three times in twenty-four hours, dissolved in distilled water, or, when there is need of a tonic, in a few drops of Huxham's tincture of bark. This should be steadily continued, with, now and then, a few days' intermission, for a number of weeks, not only until all disease is apparently gone, but for a considerable period after; and it will be well, for the sake of the more complete eradication of the poison, occasionally to recur to the remedy until the child is several years of age. When the disease proves obstinate, the bichloride may generally be advantageously conjoined with the iodide of potassium, from the fourth to the eighth of a grain of the latter being given with each dose of the salt, according to the age of the child.

When the disease appears at a late period of life, as after the eighth, tenth, or fifteenth year, the best plan is to use at once liberal doses of iodide of potassium, as from three to five grains, in combination with the tenth of a grain of bichloride of mercury, thrice in the twenty-four hours. This treatment is particularly indicated in affections of the eye,

ear, throat, nose, and bones. When corrosive sublimate disagrees, or does not seem to reach the case, the most suitable substitute is calomel.

When the body is covered with sores, pustules, or tubercles, a gentle course of mercurial fumigation will be advisable, great care being taken not to carry it to such an extent as to induce debility. Mild dressings may be used in the intervals, of which the best are nitrate of lead, iodoform, or acid nitrate of mercury, properly diluted.

When bichloride of mercury is inefficient or prejudicial, the gray powder may be employed, or, what is preferable, because not liable to cause gastro-intestinal irritation, inunctions with mild mercurial ointment, from half a drachm to a drachm being rubbed upon the inside of the thighs once a day, or a flannel bandage smeared with the ointment, or the twenty per cent. oleate of mercury may be steadily worn around the abdomen. The treatment should be persistently continued until all evidence of the disease has disappeared.

CHAPTER X.

WOUNDS AND CONTUSIONS.

SECT. 1.—GENERAL CONSIDERATIONS.

THE term wound is a generic one, employed to designate all injuries attended with a division of tissue, inflicted by sharp, pointed, or blunt instruments and weapons of every description. The breach, or solution of continuity, may be apparent or concealed; that is, upon and in the skin, as well as the more deep-seated structures, or the skin may retain its integrity, and the wound be strictly subcutaneous.

Wounds are constantly made by the surgeon in the legitimate exercise of his professional duties, as in the removal of limbs, tumors, and urinary calculi, and in the restoration of lost or mutilated parts. In general, however, they are inflicted accidentally, and hence, as this may happen in a great variety of ways, they are very properly arranged under different heads, according to the manner in which they are produced. Thus, a wound is said to be incised when it is caused by a sharp instrument; lacerated, contused, or bruised, when it is made by a blunt body; punctured, when the weapon is narrow and pointed. A gunshot wound is a breach inflicted by a ball. In a poisoned wound the tissues are inoculated with some peculiar virus, either secreted by an appropriate apparatus in the bodies of certain animals, as the bee or snake; contained in the salivary fluid, as in the dog in hydrophobia; or developed after death, as in the human subject in the dead-house. The term penetrating is employed when the wound communicates with a cavity, as a joint, the chest, or the abdomen.

Wounds are also named according to the region of the body which they occupy, or the particular tissues, organ, or cavity which they affect and interest. Thus it is customary to speak of wounds of the head, neck, chest, abdomen, and extremities; of wounds of the skin, muscles, tendons, vessels, and nerves; of wounds of the stomach, heart, lungs, liver, and brain; and of wounds of the joints, pleura, pericardium, and peritoneum. Finally, wounds may be superficial or deep; recent or old; simple or complicated; oblique, transverse, or longitudinal. The most common complications which attend wounds, or which arise during their progress, are, hemorrhage, the presence of foreign matter, abscesses, mortification, erysipelas, septicemia, pyemia, and tetanus. Such accidents, whether occurring singly or in combination, often completely change the character of a wound, rendering complex what was originally perhaps perfectly simple, and dangerous what was, in the first instance, perhaps so insignificant as hardly to attract serious attention.

The characteristic features of wounds will be pointed out in connection with the different classes of injuries to which they relate. The prognosis and treatment will also receive due attention. It will, therefore, be sufficient here to state, in general terms, that they are all productive, each in its own peculiar way, of more or less pain and hemorrhage, and that, in most cases, there is marked retraction of their edges, caused either by their natural resiliency, or by the vulnerating body. The principal exceptions to this rule are in punctured and gunshot wounds, in which, from the peculiarity of their shape, and the manner in which they are inflicted, the latter phenomenon is very uncommon.

Wounds are absorbing surfaces, a fact which should not be lost sight of during their treatment, as through them poisonous substances may readily find their way into the system, and thus either seriously complicate them, or destroy the patient. Recent skin wounds especially possess this quality, but it is hardly less conspicuous in muscular wounds. In granulating wounds the danger is less. The experiments of Renaulton on the virus of glanders and those of Dolin on that of anthrax go to show that the absorption is so rapid that cauterization performed more than ten or fifteen minutes after the inoculation is useless as a means of protecting the system. Davaine finds that punctured wounds are by far the most dangerous of all, as it respects the ingress of poisonous material, and that cauterization to be effective must be very prompt. These facts are of the greatest practical significance, as they point unerringly to the indispensable necessity of the employment of cleanliness and of free drainage in every case of this class of affections.

A not unfrequent occurrence after wounds, especially in nervous, irritable subjects, is *spasm* of the muscles, often accompanied with violent pain and twitching. Such an effect may follow upon almost any injury of this kind, however insignificant, but is most common in punctured, lacerated, and gunshot wounds, in which it not unfrequently entails the most frightful suffering. The stump, after amputation of the leg and thigh, sometimes jerks and twitches in the most distressing manner for hours and even days together ; and spasm of the muscles, in compound fractures, is one of the most common causes of displacement of the ends of the fragments, as well as, in many cases, a source of great pain and annoyance. The spasm generally occurs in paroxysms, coming on during sleep, and suddenly waking up the patient, very much as in coxalgia and disease of other joints. The muscular movements are occasionally very slight, amounting to a mere quivering of very transient duration, and unattended with any starting or jerking.

Emphysema is occasionally noticed in and around wounds. It comes on at a variable period after the receipt of the lesion, and manifestly depends upon different causes. Thus, in wounds of the neck, chest, and abdomen it is usually owing to an escape of air, respectively, from the windpipe, lungs, and intestines. In another class of cases, it is probably due to the accidental introduction of the air at the moment of the injury, or to the entanglement of the external air among the tissues from the peculiar valve-like shape of the wound. Sometimes, again, it is apparently caused by the decomposition of effused fluids ; and cases arise in which it is evidently dependent upon the gas generated during the progress of traumatic gangrene.

However induced, the exciting cause of the emphysema should always be diligently inquired into, as this must necessarily exercise an important influence upon the prognosis and treatment of the case. When present immediately after the receipt of the wound, it is evident that it cannot be due to gangrene or to the decomposition of effused fluids, but that the air must have found its way in, either from the exterior or through some natural cavity. The emphysema is generally more or less circumscribed, occurring as an irregular tumor, of a soft, crepitating character ; but cases occur, as in wounds of the neck and chest, in which it may occupy almost an entire limb, if not the greater portion of the body.

The *scars* left by wounds, even by the most simple incision, are sometimes followed by great disfigurement ; and now and then they are transformed into keloid growths, with a remarkable recurring tendency after extirpation. A cicatrice occasionally presents an unhealthy aspect from the constant irritation to which it is subjected by the friction of the patient's clothes. A morbid condition of the system, especially scurvy and anemia, may also materially influence the nature of such a product. Wounds made by glass, splinters of wood, nails, and similar bodies, are exceedingly prone to be followed by unseemly, indurated, rough, and troublesome scars.

Foreign bodies, containing coloring matter, may, if retained, leave a cicatrice permanently in a dark, unseemly condition. The principal substances likely to cause such an appearance are gunpowder and coal, both of which are often so firmly imbedded in the skin as to render it extremely difficult to dislodge them.

The nature of the cicatrice is generally materially influenced by the character of the granulations which precede its development. If these are firm and healthy, the cicatrice will be likely to be so too : but if they are large, sodden, and œdematous, it will inevitably be soft and thin, abnormally vascular, of a bluish color, and prone to ulceration and even gangrene. An imperfectly organized cicatrice of the abdomen occasionally gives way under the pressure of the contained viscera, and thus becomes a cause of ventral hernia, and the cicatrice of the large wound in certain amputations, as in those of the thigh, sometimes gives way long after the parts are apparently firmly united. Scars, to

which this description applies, are most common in feeble, anemic, or scorbutic subjects, and are evidently due to a defective state of the vital powers interfering with nutrition and the process of repair.

Painful scars are very common after amputations, owing to some peculiar change wrought in the terminal portions of the nerves after such operations. Lacerated, contused, punctured, and gunshot wounds are not unfrequently followed by similar effects. The pain, which often assumes a neuralgic character, is liable to serious exacerbations from the most trivial causes, especially exposure to cold, atmospheric vicissitudes, and disorder of the general health, and, from its persistency and obstinacy, may become a source of great suffering and annoyance, rendering life perhaps almost insupportable.

Keloid tumors, of the spurious variety, originally described by Alibert, often form upon scars without any assignable cause, even after a wound has healed apparently in the most kindly manner. The degeneration usually appears within the first few months after the closure of the wound, forming a hard, firm, irregular cicatrice of a fibrous or fibroplastic character, more or less unseemly, the seat of frequent itching and annoyance, and liable to repullulation after extirpation.

Finally, scars left after the healing of wounds sometimes take on carcinomatous action, the most common form in which it appears being the epithelial. Such an occurrence is most frequent in old scars, and especially in the scars left by burns and scalds constantly irritated by pressure, friction, and other causes of disease.

1. MODE OF DRESSING AND TREATING WOUNDS.

The most important retentive means in the treatment of wounds are adhesive plaster and sutures, aided, if necessary, by the bandage and attention to the position of the injured parts.

There are various substances which are endowed with adhesive properties, and which are therefore well adapted to retain the edges of a wound in contact with each other. Those, however, which are usually employed for this purpose are the common adhesive plaster, collodion, and isinglass plaster.

The old adhesive plaster, so long used in this and other countries, has been entirely superseded by the plaster invented by Dr. Henry A. Martin, of Boston, by whom it was formally introduced to the notice of the profession in 1877. It is essentially composed of the very best Para rubber, Burgundy pitch, and balsam of Tolu, spread upon strongly woven cloth, thoroughly shrunken and freed from every trace of dressing by treating it antiseptically. The advantages of this plaster are indisputable. It is applied without heat or moisture, adheres with extraordinary firmness, is flexible, waterproof, and devoid of irritating properties, is unimpaired by age, light, air, or temperature, and can be removed without leaving any of the adhesive matter on the skin. Mead's plaster also adheres without warming, and possesses highly adhesive properties.

The plaster is cut, as occasion requires, into suitable strips with scissors, carried in the direction of the length of the cloth, not in that of its breadth, as it is much more yielding in the latter than in the former, and therefore liable, when it becomes heated by the skin, to let the edges of the wound gape more or less. Trifling as this precept may appear, it is of great practical importance, and can, therefore, hardly be too strongly insisted upon. When the wound occupies a limb, each strip should be long enough to embrace about three-fourths of its circumference; on no account should it completely encircle it, lest it impede the return of venous blood, and cause pain and tension. The width of each strip should be uniform, and vary, on an average, from half an inch to an inch, according to the exigencies of the case.

Previously to applying the plaster, the surface of the skin should be divested of hair, and well dried with a soft cloth, as the least moisture prevents it from adhering. The shaving of the parts is necessary to facilitate the removal of the plaster, which would otherwise be difficult and painful, and which might, by its traction, even seriously compromise the safety of the adhesive process. These important preliminaries being disposed of, all bleeding having ceased, and the edges of the wound being carefully held together by an assistant, each strip is applied in such a manner that its centre shall correspond with the wound, while each extremity firmly grasps the opposite side. If the wound is very long and deep, the first strip should be stretched across the middle, which thus becomes the starting point of all the rest. The interval between each two strips should not, on an average, exceed the eighth or fourth of an inch, as this will afford ample space for the drainage of blood, serum, and lymph, of which there will generally be more

or less after every injury of this description, especially if it be of considerable extent. Care must be taken that the adhesive strips are laid down in as smooth and even a manner as possible ; hence, the parts should always be put in the position in which it is intended to keep them during the treatment. If the strips rise up in folds, or are partially detached, they should immediately be replaced by others, more skilfully applied. Finally, it is very necessary, on the one hand, not to invert the edges of the wound or to draw them together too firmly, and, on the other, not to approximate them so loosely as to endanger their partial separation. In short, everything should be done in the most neat, accurate, workmanlike manner.

Isinglass plaster is not used so much now as formerly. It is said to be less irritating than the common plaster, and equally as adhesive. Moreover, it is alleged that insinglass, if spread upon gauze, will, by its transparency, admit of complete surveillance of the wound, the surgeon being able to witness the changes going on in and around it. Notwithstanding these supposed advantages over common adhesive plaster, my conviction is that the latter, as prepared by the modern pharmaceutist, is decidedly superior to it, in every particular. The idea that common adhesive plaster is apt to provoke erysipelas and ulceration of the skin is in great measure, if not wholly, chimerical ; at all events, I have seldom met with such an occurrence. In the next place, it is much stronger than isinglass plaster, and therefore affords better support to the parts. Thirdly, it is less liable to be prematurely detached ; and, lastly, although it is opaque, yet as there is always an interval left between each two strips for drainage, it is obvious that it cannot in the slightest degree interfere with the examination of the wound and its vicinity. I, therefore, generally limit the use of isinglass plaster to the dressing of small wounds or little cuts, and employ the common plaster for wounds of large size. The principles regulating its application do not differ from those already laid down. The strips should be of appropriate length and width, and moistened on the glazed surface with a sponge pressed out of cold water.

Glycerine adhesive plaster, employed by some of our surgeons, is liable to the same objections as isinglass plaster ; it makes, however, a very neat dressing, and is well adapted to the more simple forms of wounds.

Court plaster, as it is called, is seldom used by the scientific surgeon, as, from its irritating nature, it is very apt to inflame the parts, and thus occasion overaction. It is composed of gum benzoin and isinglass, dissolved in rectified spirit, and brushed over silk, with a coating of Chian turpentine, to prevent it from cracking.

The substance known as skin plaster is well adapted as a dressing for very small, superficial wounds, as it is perfectly transparent, very smooth, and non-irritant, but is not strong enough for large ones. It is composed of sheep's omentum, coated with a solution of isinglass, and is applied to the parts previously wet with a sponge.

Collodion, first used for surgical purposes by Dr. J. P. Maynard, of Boston, in 1847, consists of a solution of gun cotton in ether, with the addition of a little alcohol. It is a transparent, colorless fluid, of a syrupy consistence, which, when applied to a dry surface, allows of the rapid escape of the ether, leaving a thin, bluish film, possessed of remarkably adhesive and contractile properties. As it is impervious to water, it is less liable to be prematurely detached than the isinglass or common plaster. Put upon wounds or abraded surfaces, it causes sharp pain, which, however, always speedily subsides. It may be applied by means of a camel-hair pencil, or a small brush, directly to the affected parts, as in the case of small, superficial cuts ; or upon strips of linen, muslin, patent lint, or Tarlton gauze, of suitable width and length, when the wound is so large and deep as to require firm support. As the ether evaporates very rapidly, the dressing should be applied with as much celerity as possible, everything being thoroughly arranged beforehand, and the edges of the wound well dried and supported by an assistant. Collodion makes an excellent dressing in wounds of the neck and face, as well as in other movable regions of the body, and in all cases where it is particularly desirable to exclude the air.

Styptic colloid, introduced to the notice of the profession by Dr. B. W. Richardson, of London, is a styptic, antiseptic, and deodorizer, and affords a complete means of excluding air from wounded or ulcerated surfaces. It is composed of xyloidine, a substance resembling gun cotton, dissolved in ether and saturated with tannic acid. Applied in a similar manner to collodion, the blood and secretions permeate the cotton as the ether vaporizes, and the albumen is coagulated by the tannic acid, forming a leathery membrane, while the cotton imparts substance and adhesive qualities to the mass. To remove the dressing, it is only necessary to moisten it with a mixture of alcohol and ether, or with alcohol and water warmed a little above the temperature of the body.

India-rubber possesses strong adhesive qualities, and an excellent plaster may be prepared from it by spreading a solution of it, with a stiff brush, upon gauze, silk, or thin muslin, after the fashion of collodion. One great advantage which it possesses over most other material is that it is completely impermeable by water.

The substance, whatever it may be, should be retained until it ceases to answer the object for which it was applied. The moment it becomes a source of irritation, loses its hold, or obstructs drainage, it should be removed, the substitute material being always properly arranged beforehand, lest the parts should be unduly exposed to the air, or insufficiently supported. Surgeons often err in being too anxious to meddle with the adhesive plaster; too early interference has a tendency to interrupt the adhesive process, and may, in persons of a bad, irritable constitution, give rise to erysipelas and other accidents. I have, more than once, after severe operations, retained all the original strips for upwards of a fortnight; until, in fact, complete cicatrization had taken place. Such good luck, however, is rare; and it more generally happens that the dressings, plaster and all, have to be changed at the end of the second, or, at furthest, the third day. Much, of course, will depend, in every case, upon the state of the weather, the size and situation of the wound, and the amount and character of the discharges.

When the wound is extensive, only a few strips should be taken off at a time, otherwise there will be danger of separating its edges. Before the dressing is readjusted, the parts should be thoroughly cleansed with tepid water, pressed from a sponge held at some distance or applied with a syringe; no wiping must be done, nor must the wound be rudely squeezed. Any matter that may be at the bottom or between its edges should be pressed out in the most gentle and careful manner, rough manipulation being not only painful, but injurious to reparative action. Sometimes the necessary cleanliness may readily be effected with a moist sponge or soft cloth passed lightly over the surface. Great skill is required in removing the plaster to the best advantage of the parts. Each strip should be raised by taking hold of one extremity with the thumb and finger of one hand, while the other hand is engaged in supporting the wound; the other end being treated in a similar manner, the portion corresponding with the wound is lifted off last, and thus all danger of injury is effectually obviated.

The principal sutures employed in surgery are the interrupted, twisted, continued, and quilled. There are several others which will be described in their proper place.

The *interrupted suture*, which is more frequently employed than any other, is made with a needle, either straight or slightly curved, and armed with a single, well-waxed ligature, either of silk or of linen, as may be found most convenient; for, in a practical point of view, it is really altogether immaterial which it is. The instrument, which should always be very sharp, and in the best possible order, is introduced through the edge of the wound, from without inwards, at a suitable distance from its surface, and then pushed from within outwards at precisely the same point at the opposite side, leaving the thread in its track. A second stitch is then to be taken in a similar manner, and thus the operation is continued until a sufficient number has been introduced, when the ends of each ligature are to be tied with a reef-knot, and cut off close. The distance at which the needle should be inserted from the wound must of course vary in different cases and in different regions of the body; but, in general, it should not be less than a line, nor more than a quarter of an inch.

Fig. 91.

Interrupted Suture.

The depth at which it is passed should be such as to admit of accurate approximation of the wound, about one-third of the thickness of the edge being behind and the rest in front of the needle. In no case of superficial wound should the instrument embrace muscular or aponeurotic substance. The interval between each two stitches must also necessarily vary, according to circumstances, from a few lines to an inch or more, and should be supported, after the sutures have been tied, with adhesive plaster, as in fig. 91. If the wound is very small, it may be sewed up with a common cambric needle, and a proportionately delicate thread.

The needles for sewing up wounds are of various forms and sizes, straight or curved, short or long, according to the object to be fulfilled, or the nature of the parts affected. For sewing up any wound of considerable size, the instrument should, as a rule, be perfectly straight, and not less than two and a half to three inches in length, with a sharp rounded point, or a point slightly curved and spear-shaped. In
certain situations, as in wounds of the face, a curved needle will be found to be most convenient. Very short curved instruments are necessary when we wish to sew up a fissure of the palate, or a ruptured vesico-vaginal septum. A needle with an immovable handle, such a one as is generally put up in our pocket cases, is a very useful instrument.

The *twisted suture* is made by introducing a pin through the edges of the wound, and passing a thread round it, so as to confine it in its place. It makes an admirable retentive apparatus, but is of more limited application than the interrupted suture. From the fact that it is generally employed in the treatment of harelip, it is often called the harelip suture.

Various instruments are employed for making the twisted suture. What is called the lady's toilet pin, a round steel pin, very sharp-pointed, and furnished with a glass head, is in the main the best; it readily penetrates the tissues, and creates less irritation than the common sewing-needle, formerly so much employed for this purpose. Fifty years ago surgeons were in the habit of using a silver needle, with a movable steel point, as seen in fig. 92; a cumbersome, awkward instrument, now happily discarded. Dieffenbach recom-

Fig. 92.

Old Suture Pin.

mended what is called the insect pin, which, however, has never come into general vogue, at least not on this side of the Atlantic. In small wounds of the forehead, face, and neck, in which it is of so much importance to prevent the occurrence of a scar, I have been in the habit, ever since I entered the profession, of employing a very delicate gold pin, with a head of sealing wax, and there is not, I am sure, any article better suited to fulfil such an indication. Insusceptible of oxidation, it causes no irritation, and may therefore be retained for almost any length of time without detriment to the parts.

Whatever kind of pin be employed, transfixion is effected in the same manner as in the common interrupted suture, the thumb and finger being generally quite sufficient for the purpose. In some situations, however, as, for example, in certain parts of the face, the operation will be greatly facilitated by the use of a special pair of forceps, or the pin-conductor, fig. 93, of Dr. Gurdon Buck, an instrument easily obtained at any of the cutler shops. The wrapping material, consisting of ordinary thread or silk, smooth and well waxed, to prevent the imbibition of the secretions, is wound around the pin elliptically, as in fig. 94, as it arranges itself much more evenly and efficiently when thus applied than when it is carried around the pin in the form of an 8, as in fig. 95, and as is so gene-

Fig. 93.   Fig. 94.   Fig. 95.

Buck's Suture Pin-Conductor.   Twisted Suture.
rally done in this and other countries. As many pins or needles having been inserted as may be deemed advisable, the threads are passed from one to the other diagonally across the gap, so as to effect complete apposition there also, and so obviate the necessity for using adhesive plaster. Finally, the threads being tied, the operation is completed by cutting off the points of the pins with a pair of pliers, fig. 96, otherwise they may hurt the patient, or be caught in his clothes.

Instead of confining the pin with a thread, Rigal uses a thin narrow ring of gum elastic, which answers the purpose most admirably, as it draws the parts firmly and evenly together. The only objection to it is that it may cause too much pressure when there is an unusual amount of swelling in the lips of the wound. The late Dr. Washington L. Atlee employed this form of suture in many of his ovariotomy cases, under the impression that it possessed decided advantages over the more ordinary contrivances. The annexed cut, fig. 97, exhibits the shape and mode of application of the ring.

The period during which the pins are retained varies from two to three or four days, according to the circumstances of the case. Their removal should be effected with great

Fig. 96.
Pin Pliers.

Fig. 97.
India-rubber Sutures.

care, in a direction contrary to that of their introduction, the parts being well supported at the time. As the threads are generally firmly glued to the surface and edges of the wound, it is well to let them remain until they drop off of their own accord, as they usually do in a day or two after the withdrawal of the pins. The support thus afforded is often of great service to the imperfectly organized bond of union, and its premature removal sometimes necessitates the employment of adhesive plaster, or the insertion of a new pin.

The *continued suture*, fig. 98, is similar to that used by the glover, on which account it is generally known as the glover's suture. It is made with a needle armed with a suitable thread, which is passed diagonally from one side of the wound to the other, on the same principle as in the interrupted suture. Its use is almost exclusively restricted to the treatment of wounds of the intestines, in connection with which it will again be noticed.

Fig. 98.

The Glover's or Continued Suture.

Fig. 99.

Quilled Suture.

The *quilled suture*, fig. 99, so called from the fact that it was originally made with the assistance of two quills, is employed chiefly in the treatment of lacerations of the perineum, with a view of effecting more even and accurate contact of the opposed surfaces. The older surgeons were in the habit of using it in sewing up deep muscular wounds, as those of the thigh and abdomen. No one, however, thinks of resorting to it for such a purpose at the present day; for in the latter case the object can be attained much more easily by the ordinary interrupted suture, extending down nearly to the peritoneum, and in the former by methodical support with the compress and bandage. The quilled suture is made by passing a stout double thread through the sides of the wound, at intervals of an inch or an inch and a half, and tying its ends over a piece of bougie, quill, wood, or whalebone, lying parallel with the cut, but about half an inch from it.

Although sutures undoubtedly act as foreign bodies, necessarily exciting a certain degree of irritation in the tissues into which they are inserted, I have by no means that

dread of them which they seem to have inspired in the minds of many practitioners. I have rarely witnessed any ill effects from their employment, and when anything of the kind did occur, the fault was generally due more to the indiscretion of the surgeon, or to the want of stamina on the part of the patient, than to any untoward operation of the sutures themselves. Provided the threads, or needles and threads, are clean, of suitable size, and properly inserted, the constitution of the patient in good condition, and the wounded structures in a tolerably sound state, it is difficult to understand how they could become a source of serious irritation, much less of erysipelas or severe ulceration, effects which have all been charged to their action. It is, therefore, I conceive, a good plan to use them freely, and to allow them to remain so long as they seem to answer the purpose for which they were introduced. The moment this object is attained, or they are found to be productive of injury, they should be withdrawn.

The best material for sutures unquestionably is metal, and it matters not, according to my experience, whether this is silver or iron, provided it is properly tempered, perfectly smooth, and sufficiently thin and pliant. This substance, although noticed in connection with this subject by different writers, was first introduced into regular practice by Dr. J. Marion Sims, and is one of the greatest additions to the armamentarium of the present day.

The advantages of the metallic suture over every other are that it is entirely free from all irritating properties, and that it may be retained for weeks or even months, as I have repeatedly known it to be, without provoking suppurative action, so common when silk or thread is employed.

In England, at the suggestion of Mr. Clover, a very thin copper wire covered with gutta percha—in fact, a miniature telegraph wire—is occasionally employed for closing wounds. It does not cause any irritation, is easily introduced with a fine sewing-needle, and is so soft as to be readily cut and tied into a knot, like ordinary thread.

Wire is introduced in the same manner as thread, the short end being firmly twisted round the long one ; or, instead of this, it is tied with a double knot, as may also be readily done when the wire is very thin and flexible. Numerous needles have been devised for facilitating the insertion of the wire, but it is questionable whether they possess any particular advantage over the one in common use. Perhaps the most unexceptionable one is one with two holes, with a vertical groove on each side.

The annexed engravings will serve to convey an idea of some of the best forms of this kind of needles. Fig. 100 represents Mr. Price's instrument ; it is grooved on both sur-

Fig. 100.

Price's Needle for Wire Suture.

faces, and is pierced with two holes, nearly half an inch apart, the wire being passed from the lower to the upper, and then doubled and twisted at the end to hold it. Mr. Murray's needle, fig. 101, has a groove and open box end, while Mr. Lister's, fig. 102, has a single

Fig. 101.   Fig. 102.
Murray's Needle.   Lister's Needle.

eye and a groove on the side. Ingenious contrivances of a similar kind have been constructed by Dr. Levis and Dr. Goddard, of this city.

For introducing wire, both in superficial and deep-seated wounds, the tubular needle, represented in fig. 103, will be found a convenient instrument.

In removing the wire suture, care must be taken that the edges of the wound be not forcibly separated. To prevent this, the loop should be cut on one side very close to the border of the wound, when the twist may be seized with the forceps, and the wire gently

drawn out. The length of time during which the suture is retained must depend upon circumstances. From three to five days is a good average period.

Fig. 103.

Tubular Needle.

Horsehair prepared by boiling for a short time in a weak solution of sodium, is occasionally employed as a material for the interrupted suture, and answers excellently well, as it is sufficiently strong for any wound, however large or deep, and does not absorb fluids or cause irritation. It may, likewise, be retained indefinitely. To prevent the ends from untying themselves, the reef-knot must be used.

Carbolized catgut is now being employed as a material for sutures in connection with the antiseptic treatment of wounds; but it should be prepared with chromic acid in order that it may resist the solvent action of the tissues until the process of union is completed.

Rest and easy position are essential elements in the treatment of wounds. If the part be exercised, or moved, it will be difficult, if not impossible, to preserve apposition, and to limit inflammatory action. If the wound be transverse, and seated in an extremity, it will inevitably be torn open, if the muscles which pass along it are not maintained in a relaxed condition. Thus, if the wound involve the front of the thigh, the limb is extended, and flexed if it affect the posterior aspect; the muscles immediately concerned in the lesion being thus in each case put in a state of perfect repose.

In very large and deep wounds, it is hardly possible to keep the edges in contact, in their entire extent, without the aid of compresses and bandages, more especially when they involve large and numerous muscles, as, for example, in wounds of the thigh. In such a case, adhesive plasters and sutures, however skilfully applied, would scarcely be sufficient to afford the parts the support which is necessary to maintain them in perfect apposition. More or less separation would almost be inevitable. To fulfil this indication, so important to the adhesive process, it is indispensably necessary to lay a stout compress or piece of sponge along each side of the limb, opposite the deep portion of the wound, and to confine it with a roller, extending from the toes upwards as far nearly as the groin. In all lesions of this description, whether the result of accident or of operation, great care must be taken to prevent the retention of fluids, otherwise suppuration will take place instead of union by the first intention. Large intervals should be left between the adhesive strips, and holes should be cut in the bandage where it lies over the affected part: in some cases, indeed, it will even be necessary to leave a small tent or tube at the bottom of the wound, at the most dependent point, to drain off the discharges.

Fig. 104.   Fig. 105.

Invaginated Bandage for Longitudinal Wounds.

The most suitable bandage for supporting wounded parts is the common roller, carried upwards from the distal portion of the limb to a short distance beyond the seat of the injury. The invaginated bandage, represented in figs. 104 and 105, and formerly so much in vogue, is a dangerous contrivance, unworthy of scientific surgery.

When all foreign substances have been removed, when hemorrhage has been checked, and when its surfaces have been accurately approximated without tension, and are properly supported, due provision having been made for the escape of the secretions, a wound is placed in the best possible condition for repair, and the less it is interfered with the more likely will it be, all other things being equal, to do well. Meddlesome surgery cannot be too pointedly condemned, for it is hardly less pernicious than the slovenly surgery still so common at the present day, especially in private practice. The modern treatment of wounds has been carried to the very verge of simplicity, and it is difficult to see how it could possibly be improved, although it is doubtless still susceptible of important modifications. When the

parts are merely divided, all that is generally necessary is to put them in accurate con-
tact, and to maintain them for a certain period in an easy, elevated, quiet, and relaxed
condition. When the wound is very large, as after the amputation of a limb, or the
extirpation of the mammary gland, I generally cover the surface with a pledget of lint
wet with olive oil or cosmoline, to prevent the contact of the air and thus diminish the
chances of profuse suppuration.

I have never found any appreciable benefit in such a case from the use of antiseptic
dressings, although they are regarded by many surgeons as most valuable accessories.
The antiseptic method, when strictly adhered to, demands rigid attention to minute
details, so that it has been modified in various ways, of which the most popular appears
to consist in irrigating or washing the wound with a solution of carbolic acid, boracic
acid, salicylic acid, benzoic acid, thymol, oil of eucalyptus, chloride of zinc, or pure
alcohol, and afterwards enveloping the part in cotton-wool or absorbent cotton. The
merits of ordinary cotton-wool in preventing the ingress of microscopic organisms from
the surrounding atmosphere are justly praised by Guérin, Gamgee, Little, of New York,
and the late Dr. Green, of Portland, and it is also certainly useful for affording gentle
and systematic compression. At the present day, carbolic acid is falling into desuetude.
As I have pointed out in the section on septicemia and pyemia, it does not prevent the
development of micrococci and bacteria in the pus of wounds, and its employment has
not only frequently given rise to serious symptoms of poisoning, but it has been followed
by death in a number of instances.

Cold water-dressing may be required, with a proper regulation of the diet and a mild
aperient when there is danger of overaction. In contused, lacerated, punctured, and
gunshot wounds, cold water-dressing, either alone or in union with opium, arnica, lauda-
num, or laudanum and acetate of lead, may generally be advantageously employed from
the beginning; or, instead of this, warm water or a cataplasm may be used, especially
when there is a tendency to suppuration or sloughing. Leeching and more active general
means, with opium to allay pain and to induce sleep, may be required when high in-
flammation with violent traumatic fever arises, provided there has not been any severe
shock or great loss of blood. The dressings must not be allowed to become hard and dry
over the wound, nor should they oppress by their weight, otherwise they will be sure to
prove hurtful and offensive. The discharges should be frequently removed with the
sponge or syringe, the sickly odor exhaled from the raw surfaces being neutralized by the
proper use of the chlorides, Labarraque's solution, or weak lotions of permanganate of
potassium. The atmosphere of the patient's apartment should be kept in as sweet and
pure a condition as possible by attention to ventilation; in short, everything should be
done to promote nature's efforts at restoration.

If the action in the wound be languid, some mildly stimulating wash must be employed,
as a drachm of tincture of myrrh to a pint of water, a weak solution of nitric acid or
nitrate of silver, or the red lotion, as it is termed, consisting of two grains of sulphate of
zinc to the ounce of water, with a sufficiency of spirit of lavender to give it color and
fragrance. Creasote water is also a very efficient application, and occasionally nothing
answers so well as water and alcohol, water and spirit of camphor, Labarraque's solution,
or a solution of chloride of zinc, in the proportion of two to five grains to the ounce of
water. Most of these lotions are highly detergent and antiseptic, exciting new action,
allaying fetor, and promoting the granulating process. Conjoined with these remedies must
be proper constitutional means, as a generous diet, wine, porter, or brandy, and quinine,
either alone, or, what is better, combined with tincture of chloride of iron. Such treat-
ment, which will often be demanded even in the more simple cases of wounds, is impera-
tively required when there has been excessive shock or great loss of blood, causing a
severe drain upon the nervous and vascular systems, with a tendency to a low form of
fever, erysipelas, septicemia or pyemia.

A wound sometimes assumes a diphtheritic aspect, becoming incrusted, either uniformly
or in patches, with unorganizable lymph, of variable thickness and consistence, and of a
yellowish, whitish, or greenish color. The occurrence is commonly associated with the
diphtheritic diathesis, and is most frequently met with in persons of a dilapidated consti-
tution, especially among the inmates of crowded, ill-ventilated hospitals, in which it
occasionally exhibits an epidemic tendency, so that hardly any open surface, whether
recent or chronic, or however induced, escapes. Blisters, leech-bites, and the little wound
made in venesection, have all been known to be promptly invaded by it during the pre-
valence of this tendency.

When a wound is thus attacked, it at once puts on an unhealthy appearance; the pro-

cess of repair is effectually checked ; and the discharge either dries up, or assumes a serous, bloody, or ichorous character, at the same time that it exhales a mawkish, sickening odor. Any granulations that may have existed are speedily destroyed, or transformed into pale, flabby bodies, enfeebled and partially devitalized. The edges of the wound are swollen and œdematous, while the surrounding surface is inflamed and not unfrequently erysipelatous. In the more severe forms of this complication, the parts run into phagedena, if not into actual gangrene ; the pain is unusually severe; and the system soon falls into a low, typhoid condition, either eventuating in death, or in ultimate but tardy convalescence.

The treatment consists in isolation of the wounded, the employment of supporting measures, especially iron and quinine, the application of local stimulants, as nitrate of silver and lotions of permanganate of potassium, acid nitrate of mercury, or chloride of zinc, and free ventilation of the infected apartments.

Erysipelas, as a consequence of a wound, usually sets in within the first forty-eight hours after the accident, in the form of a reddish blush of the skin accompanied by the formation of delicate vesicles, a slight burning, itching pain, and more or less swelling, the point of the finger readily leaving its impression upon the affected surface. The wound soon assumes an unhealthy aspect, the discharge seemingly decreases or altogether disappears, and the plasma that is poured out is speedily devitalized. The constitutional symptoms are denotive of a depraved condition of the bloodvessels, and, in the more severe cases, typhomania often makes its appearance early in the attack. Occasionally the erysipelas breaks out upon the body of the patient without invading the wound, and such cases, of which a considerable number have fallen under my immediate observation, are generally peculiarly dangerous, as they are indicative of an uncommonly disordered and depraved state of the system. The chief remedies in the treatment of traumatic erysipelas are quinine and iron with milk punch, beef essence, and fresh air, and the application of iodine with emollient cataplasms and solutions of acetate of lead, frequently renewed.

If the wound be assailed by gangrene or phagedena, the topical remedies most likely to prove useful are nitric acid, carbolic acid, nitrate of silver, bromine, iodoform, permanganate of potassium, and acid nitrate of mercury, the latter being especially entitled to our confidence for its well-known efficacy in arresting morbid action. Sometimes these substances may be advantageously employed in a pure state ; in general, however, they should be very greatly diluted, otherwise they will be productive of severe suffering, if not also of positive injury.

The cicatrization of a granulating wound may generally be very materially expedited by skin-grafting, performed after the manner described in the chapter on Minor Surgery. The operation is especially adapted to cases attended with great destruction of integument. As many as a dozen, fifteen, or even twenty grafts may be inserted at one time, at a distance of eight or ten lines from one another ; repetition being occasionally effected if the cicatrization do not advance sufficiently rapidly.

The spasm and jerking consequent upon wounds, whether accidental or inflicted by the surgeon's knife, are best controlled by anodynes, especially hypodermic injections of morphia, the bromides, chloral, valerian, and choloroform, with the addition of the bandage and lotions of aconite and laudanum. Attention to posture is generally of great moment ; and in many cases, especially in the treatment of wounds after resections of the joints, in compound fractures, and dislocations, ease and perfect rest can only be secured by means of splints.

The emphysema which occasionally follows upon such injuries must be treated according to the nature of the exciting cause. In general the air gradually disappears spontaneously ; when it does not, and the symptoms are at all urgent, relief must be sought by a few punctures or small incisions.

Unhealthy scars, the result of unsound granulations, and other causes, must be treated with solid nitrate of silver, or some slightly stimulating unguent, as the dilute ointment of nitrate of mercury, aided by multiple punctures or scarifications and gentle compression. Hard, elevated, unseemly scars must be removed with the knife, the wound being afterwards treated upon general principles. Before doing this, however, great care should be taken to prepare the system properly, otherwise the parts may be seized with erysipelas, or a bad cicatrice may be succeeded by a worse one.

Scars left by incised wounds inflicted in early life, whether accidentally or designedly, generally completely disappear with the progress of age. The inodular tissue, unless very abundant, gradually assumes the properties of the native structures in its vicinity, and eventually resembles them so closely as to render it impossible to detect any difference.

When a vessel of considerable size is divided, the only plan is to secure it at once with

a suitable ligature. If some time, however, has elapsed since the occurrence of the injury, the artery will not only be inflamed and more or less softened in its texture, but materially changed in its relations by deposits of lymph, and, perhaps, even by the presence of pus. A ligature, applied to a vessel in such a condition, will be almost sure to be detached before the natural process of repair has advanced sufficiently far to form a firm internal clot. Besides, the difficulty of finding such a vessel is generally very great. A tedious dissection, often painful and bloody, is required to expose it; and when, at length, the object is attained, the surgeon has the mortification to discover that it does not answer the purpose. The parts slough or ulcerate, the ligature is cast off prematurely, and a copious hemorrhage again ensues; and thus the case is apt to continue until the patient is completely exhausted. Instead of pursuing such a useless and dangerous course as this, no time should be lost in securing the affected vessel by acupressure, the needle being passed underneath it in such a manner as to include a large quantity of the neighboring tissues. This may occasionally be done, as when the vessel is comparatively superficial, without any previous dissection, by pushing the needle through the skin. It is just in such a case as this that acupressure, I conceive, finds its chief advantage; effectually arresting the flow of blood, and yet not, like the ligature, irritating the artery.

When the case does not admit either of ligation or of acupressure, the only resource is the employment of styptics and systematic compression, which often answer the purpose very satisfactorily, even when the hemorrhage proceeds from an artery of considerable magnitude, as, for example, the axillary or brachial. Dr. James M. Holloway, formerly of the army, has adduced a number of instances of consecutive and indeterminate hemorrhage, consequent upon gunshot wounds, treated successfully in this way, and my own experience fully corroborates the propriety of the practice. His paper upon the subject may be found in the American Journal of the Medical Sciences for October, 1865, and is well worthy of an attentive perusal.

The development of *maggots* in wounds occurs chiefly in hot weather, but I have also seen it in the autumn and early part of winter, in consequence of the artificial heat of the patient's apartment. In tropical climates the formation of maggots in wounds and ulcers is almost unavoidable, despite the best directed efforts to prevent it. The soldiers in Egypt and Syria, under Larrey, and our troops during the war with Mexico, suffered greatly from this cause. Dr. Proctor informed me that wounds, however carefully cleansed in the morning, were found, in the evening, to contain large numbers of these worms, and, if the slightest neglect took place, they speedily collected in incredible quantities, and of prodigious size, their diameter equalling that of a small goose-quill, while their length ranged from three to nine lines. The soldiers had a great horror of them, and, from the disposition which they evinced to burrow deeply among the muscles, they were productive of no little pain and distress.

The best preventive of this occurrence is cleanliness, with a frequent change of dressing, and burying the affected parts in light bran, or carbolized dry earth, so as to place them beyond the reach of flies, which, under almost any other mode of management, are sure to find their way to the wounded surface, the slightest crevice affording them access to the much coveted spot. Moisture and a high temperature are the causes which most rapidly conduce to the formation of maggots. The means that prove most destructive to them are olive oil, spirit of turpentine, creasote, and alkaline solutions, particularly chlorinated sodium. Dr. Atkinson, of the British army, has found no remedy so efficacious as calomel, sprinkled upon the wound, or blown into it from a quill. Dr. Neudörfer, formerly Surgeon-in-chief of the Austrian army in Mexico, informs me that the most speedily destructive remedy he has ever tried is petroleum. Olive oil would probably be quite as effective.

Wounded persons should never be crowded together in the same apartment, as the effluvia arising from their sores, their persons, and their excretions cannot fail to contaminate the atmosphere, and thus become a prolific source of disease and death. Much of the mortality attendant upon gunshot wounds, in times of war, when segregation of the wounded is impracticable, is doubtless due to this cause. Wounds in syphilitic persons are occasionally slow in healing, and may, if irritated, assume the characteristics of syphilitic ulcers. The proper remedy, in such an event, would be a mild mercurial one.

The fever which follows upon these lesions, usually called traumatic, wound, or surgical fever, is greatly influenced in its character by the violence of the injury, the amount of shock and loss of blood, the nature of the parts involved, the constitution of the patient, the condition of the atmosphere, and the nature of the after-treatment. Arising generally within the first six or eight hours after the accident, it is commonly ushered in by slight

chilly sensations, alternating with flushes of heat, and succeeded by disturbance of the pulse, headache, anxiety, thirst, restlessness, heat of skin, loss of appetite, and scanty, high-colored urine. The pulse is usually strong and full, except when there is great depression of the vital powers, when it is generally very feeble, small, frequent, jerking, or even somewhat wiry. The bowels are constipated, the sleep is disordered, and the mind often wanders. Such a fever is well designated as sthenic, in contradistinction to the asthenic, so commonly met with in all low states of the system, whether induced by violent contusions and lacerations, suppurative inflammation, erysipelas, pyemia, the penetration of a large joint, the extravasation of some irritating fluid, as bile or urine, or the coexistence of serious internal disease.

Typhoid traumatic fever, always an occurrence of evil import, is essentially characterized by delirium, frequently of a low-muttering character, dryness of the tongue, sordes on the gums and teeth, tympanites, excessive thirst, nausea, want of appetite, great feebleness and frequency of the pulse, and coldness of the extremities, with a sense of excessive exhaustion. The wound in such a condition of the system has always an unhealthy appearance; the granulations, if there be any, are pale, flabby, and œdematous, while the attendant discharge is thin, sanious, watery, and offensive, exhaling an odor not unlike that of a macerating tub.

2. HEALING OF WOUNDS.

The parts having been properly adjusted, the duty of the surgeon, as far as manipulation is concerned, is temporarily at an end. Nature, the physician of wounds, as she was called by Paracelsus, must do the rest. "Warily," says this eccentric man, in his "Great Surgery," published in 1536, "warily must the surgeon take heed not to remove or interfere with Nature's balsam, but protect and defend it in its working and virtue. It is the nature of flesh to possess in itself an innate balsam which healeth wounds. Every limb has its own healing in itself; Nature has her own doctor in every limb; wherefore every chirurgeon should know that it is not he, but Nature, who heals. What do wounds need? Nothing. Inasmuch as the flesh grows from within outwards, and not from without inwards, so the surgery of wounds is a mere defensive, to prevent Nature from suffering any accident from without, in order that she may proceed unchecked in her operations." If these sentiments, uttered more than three centuries ago, could only be firmly impressed upon the mind of the modern surgeon, there would be much less meddlesome practice of every kind than there is now, notwithstanding our boasted knowledge, and our contempt for the fathers of the profession.

Modern surgeons have described five distinct modes in which wounds are supposed to heal. The first is by immediate union, or the direct growing together of the raw surfaces; the second, by scabbing, or the formation of a crust of blood upon the wound; the third, by the effusion of lymph, and the conversion of this substance into connective tissue; the fourth, by granulation, and the development of epithelial matter; and the last, by the junction, coalescence, or inosculation of granulation with granulation. The old doctrine, so ably advocated by Hunter, and so long entertained by practitioners generally, assumes that there are only two modes of cure; the one consisting in union by the first intention, primary adhesion, or adhesive inflammation, and the second in the formation of granulations, filling up the gap, and thus repairing the injury, the last stage of the process being the development of new skin. This latter mode of repair constitutes what was so long known in the schools as union by the second intention, or union by granulation.

The idea that *immediate union* of a wound may occur was first advanced by Dr. James Macartney, of Dublin. It assumes that two raw surfaces, laid closely and evenly together, will promptly coalesce with each other, independently of inflammation and effusion of plasma, vessel inosculating, as it were, with vessel, muscular fibre uniting with muscular fibre, skin adhering to skin, and nerve becoming again continuous with nerve. It is alleged, it is true, that this occurrence is uncommon, and that it requires for its production complete homogeneity of tissue, a good constitution, an entire absence of local inflammation, and the greatest possible caution in the management of the parts. When these conditions are present, it is asserted that even large wounds, such, for example, as are made in the extirpation of the mammary gland, or the amputation of the thigh, are capable of this kind of union, an assertion which is contrary alike to sound reasoning and correct observation. In discussing this question, it must be borne in mind that different textures possess, as is well known, different faculties of furnishing plastic matter, as well as of removing it after it has been deposited. Thus, in amputation of the leg, when the flap is

exposed to the air, the muscles, fibrous membranes, skin, and connective tissue are much more rapidly glazed with lymph than adipose substance, vessels, or bone, the latter of which, in fact, rarely exhibits any evidence of its presence under several days.

If we take into consideration all the circumstances that can be brought to bear upon this question; the fact that all injuries whatever are followed by inflammation, if the patient survive their effects long enough, as well as by more or less effusion of lymph; that some structures take on this action more readily than others; that inflammation is often slight in one part and severe in another; and that lymph, when no longer of any use, is invariably absorbed, nature abhorring a substance which she does not need, as in the case of a wound after the completion of the solidifying process; I conceive it to be impossible for any wound, however induced, situated, or treated, to heal by immediate union, or without the intervention of a certain degree of inflammation and more or less deposit of lymph.

The only case, it appears to me, in which such a mode of union would be at all likely to occur, is where the edges of the wound, as, for instance, one of the hand, are carefully approximated immediately after the receipt of the injury, thus affording the vessels and other structures an opportunity of promptly regaining by their homogeneity their natural relations. But even here it is more rational to conclude that the vessels, irritated and fretted by the injury which they have sustained, would furnish a thin film of lymph, serving as a bond of union between the divided parts.

The second mode in which a wound is supposed to be capable of healing is by *scabbing*, and here, also, the cure, it is alleged, is effected without the intervention of inflammation, or a deposit of plastic matter. The blood, coagulating upon the surface of the wound, soon forms a hard, solid crust, which thus protects it from the contact of the air and other injurious influences until it is covered with new skin, when nature's shield, now no longer required, is cast off as an effete substance. This mode of healing is rare in man, but sufficiently common in the inferior animals, as the horse and cow, which are so much less liable to active inflammation and its consequences. It is occasionally imitated by the surgeon's dressing, consisting of lint dipped in blood, or smeared over with collodion, so as to protect the raw surface from the contact of air and dirt. The principal proof of this mode of cure rests upon the assumption that any inflammatory deposits occurring in a case of this kind would effectually destroy the process by prematurely detaching the scab, and so leading to the development of granulations, or union by the second intention. There is, however, no positive evidence that this is the fact, and to my mind the whole theory is a mere speculation, unsupported by a single proof. The difference between such a wound and an ordinary open one is simply this, that, while in the former there is very little inflammation, in the latter there is a good deal, but in neither is it wholly absent.

With regard to the third mode of cure, or union by *adhesive inflammation*, all pathologists are agreed. The only conditions which it demands for its speedy and successful accomplishment are, first, that no coagulated blood shall intervene between the contiguous surfaces, and, secondly, that the part and system shall be maintained in such a state as to keep the inflammation strictly within the limits of healthy lymphization. According to this doctrine, union cannot take place without more or less inflammation and the effusion of a certain amount of plastic matter, serving as a bond of connection between the opposed surfaces, glazing and gluing them together, and ultimately, after having enjoyed the properties of nucleated blastema, assuming the character of connective tissue. Now, if the above views be correct, it follows that all union is the result of adhesive action; that is, of a certain degree of inflammation just sufficient, and no more, to supply the requisite amount of lymph for effecting the cohesion of the raw surfaces. If the quantity of this substance is very small, or its vitality is greatly impaired, no union can occur; nor will such an event take place if the effusion be attended with high excitement; for then the material that is poured out will either be aplastic or it will be converted into pus, thus causing the parts to gape and compelling them to heal by granulation, or union by the second intention. In the more favorable cases of adhesive inflammation, the intervening substance is soon removed by absorption, without being transformed into fibrous tissue, which can only be needed when the union is tardy, or when it is effected through the medium of an inordinate quantity of plastic material; when, in short, the apposition has been somewhat imperfect, and yet not so unfavorable as to offer any serious obstacle to cohesion, or to cause suppuration. When the process of reunion goes on kindly, the merest conceivable film of lymph is generally sufficient; the vessels, nerves, and absorbents rapidly extend from one side to the other across the intervening substance, and as soon as coalescence has occurred, and complete interchange has been established, the new

matter, now no longer needed, is speedily removed in the same manner and for the same reason that the callus is removed after the union of a broken bone; nature, as already stated, being averse to the retention of anything that is useless.

The fourth mode according to which wounds may heal is by the *granulating process*, or union by the second intention. This occurs in all cases where the adhesive inflammation is thwarted, whether from defective action, mismanagement, or any other cause whatsoever. The surface of the gaping wound is gradually covered with granulations, by which the cavity is ultimately filled up, cicatrization constituting the last act of the process.

Finally, it is contended that a wound may heal by *secondary adhesion*, as when the granulations covering its surface are closely approximated and held together by appropriate dressings. In this way, as is alleged, an opportunity is afforded these bodies of growing, as it were, into each other, by an interchange of their respective constituents. To my mind, however, this mode of union does not differ, in any respect, from the process which occurs during the development, aggregation, and cohesion of the granulations upon the surface of a suppurating wound or of an ulcer treated in the ordinary manner. In neither case is the coalescence direct, but intermediate, the connecting bond being a thin film of lymph, similar to that interposed between the raw edges of a recent wound.

If what has now been said be true, it necessarily follows that there are only two modes in which wounds unite, long recognized by surgeons, easily comprehended, and in perfect accord with the results of observation and experience. These two modes are, as was previously stated, adhesive inflammation, or union by the first intention, and repair by granulations, or union by the second intention; in other words, there is no form of union without inflammation and lymph; and the only difference in the two processes here mentioned is that in the one the plastic matter serves as a direct bond of connection between the opposed surfaces, while in the other it is converted into a series of elaborately organized bodies which, by their coalescence, ultimately fill up the gap left by the retracted edges of the wound.

A subcutaneous wound heals in the same manner as an open one, only that, as the air is excluded, there is less inflammation and more rapid cell-growth and repair. Suppuration and sloughing are seldom looked for in any of the more simple forms of such a lesion.

SECT. II.—CONTUSIONS.

A contusion is an injury produced by the sudden and forcible contact of a body, as a club or bludgeon, with a blunt surface, attended with an effusion of blood, but not with any wound of the skin, or, if a wound exist, it is so slight as to be hardly appreciable. When the skin is divided, the lesion constitutes what is called a contused wound, or a contused and lacerated one. A contusion may affect any of the structures, superficial as well as deep, hard as well as soft, cutaneous and connective tissues, muscles, nerves, bloodvessels, fibrous membranes, bones, and viscera, presenting itself in various forms and degrees, at one time slight and at another severe, according to circumstances, more especially the violence of the blow and the amount of resistance offered by the parts struck.

The causes of contusions are of a very numerous and diversified character. Among the most common are blows and falls, and machinery in rapid motion. A pinch with the thumb and finger, or a light stroke with a hammer, affords a good illustration of a slight injury of this kind. The effect of long-continued pressure in the production of contusions is well exemplified in what so often occurs in the child's head in laborious parturition, by which the scalp is severely bruised, and more or less blood is extravasated underneath the tendon of the occipito-frontal muscles. From the same cause the vagina often suffers, the bruised structures taking on inflammation, which, in some of the worst cases, terminates in sloughing, and in the establishment of vesico-vaginal fistule. The prostate gland, as every lithotomist knows, is sometimes badly bruised in the extraction of a urinary calculus, either because of its large size, or from the maladroit use of the forceps. A severe contusion may be produced by the mere concussion of an organ, as, for instance, the brain in injuries of the skull, or the testicle in riding on horseback, from the forcible contact of the organ with the saddle

Contusions vary much in degree. In the milder forms there is simply a little discoloration of the surface, or the subcutaneous connective tissue is slightly infiltrated with blood, or a small quantity of blood is collected at a particular spot, all of the unnatural appearances subsiding in a few days, either spontaneously or under the influence of some gently stimulating lotion. In the second degree, as it may be regarded, the lesion is more serious and extensive, there is greater change of texture, a larger quantity of blood is poured out, or

an artery of considerable size is laid open and a diffused aneurism is formed, contusion and laceration of tissue coexisting. In the worst degree, the soft structures are completely disorganized, mashed, or pulpified, and, if life is not speedily destroyed by shock, or shock and hemorrhage, they are soon assailed by mortification. Injuries like these are most commonly produced by falls from a great height, by the passage of the wheel of a carriage, or by the contact of a partially spent cannon ball. The skin in these frightful accidents generally participates in the lesion; but now and then an instance occurs in which, owing to its elasticity, it remains intact, although the underlying structures may be irretrievably damaged. The internal organs, as the liver and spleen, are not unfrequently fatally contused by a blow or a kick, without the faintest trace of injury of the skin where the violence was inflicted. The lungs and the brain occasionally suffer in a similar manner.

Some persons are so peculiarly constituted as to suffer from contusions from the most trivial causes, as the slightest blow, pinch, or pressure, as in sitting on a hard chair, or lying on a hard, uneven mattress. Old, fat, anemic women, with a very lax and delicate skin, are peculiarly liable to suffer in this way, some indeed almost habitually, more especially on the back, arms and thighs. Scurvy, wasting diseases, the hemorrhagic diathesis, and, in fact, all affections attended with an impoverished condition of the blood, may be enumerated as so many predisposing causes of these occurrences.

The shock in contusion is not always in proportion to the gravity of the accident, the degree generally depending more upon constitutional peculiarity than any thing else. In violent cases, as when an important viscus or a large joint has been crushed, it may be so great as to prove fatal, either speedily or after a feeble attempt at reaction.

The effects of contusions are primary and secondary, and in both cases they may be slight or more or less severe, if not fatal. Contusions involving the skin, or the skin and subcutaneous connective tissue, are always attended with a certain degree of discoloration, purplish, black, or reddish at first, but gradually, as the blood causing it disappears, shading off into bluish, olive, greenish, or brownish yellow, until it finally vanishes. When the blood is situated among the muscles, the discoloration may not show itself for several days, and even then it does not always appear at the part hurt, but perhaps at a considerable distance from it, the fluid gravitating along the easiest route towards the surface.

In nearly all contusions there is more or less swelling, the degree being usually in proportion to the degree of violence, the nature of the affected structures, as their laxity or density, and the amount of extravasated blood. Its advent, as well as its departure, may be sudden or gradual. In the former case it may be due solely to effusion of blood, but generally there is, in addition to the blood, a rapid exudation of serum, or of serum and fibrin, and also great distension of the vessels, the whole contributing to the formation of what is vulgarly called a bump, so common about children's heads as an effect of blows and falls. When the swelling is slow, it is usually attributable, especially in the absence of inflammation, to the gradual accumulation of blood, in consequence of the rupture of the injured vessels under the pressure of their contents. There is no doubt, however, in all such cases more or less exudation.

The contused structures have generally a feeling of numbness, especially if largely supplied with nerves. When the injury is slight, the sensation is commonly very transient; but now and then it lasts indefinitely, and is a source of intense suffering, as is so often witnessed in contusions of the scalp, tibia, knee-joint, spine, and shoulder. Partial and even complete paralysis and loss of sensation may exist when a large nervous trunk is severely contused.

The pain consequent upon contusions is usually very slight and evanescent, passing off soon after the receipt of the injury. It is only in exceptional cases that it is at all severe in the first instance. As a secondary effect it is sometimes very troublesome, especially in contusions of the back of the head, often assuming a neuralgic character, increased by pressure, atmospheric vicissitudes, and disorder of the general system, and liable to periodical exacerbations. A contused joint, eyeball, and bone are frequently the seat of severe local distress long after the occurrence of the primary lesion.

The amount of blood effused in this accident may be very slight, on the one hand, or very copious, on the other, depending as already stated, upon the extent of the vascular involvement and the laxity or firmness of the connective tissue. In the milder forms of contusion the blood stagnates in the capillary vessels of the skin, or is effused into the connective tissue below, so as to cause merely a little discoloration of the surface, discoloration as is witnessed, for example, in a bruise of the scalp or in the " black eye " of the pugilist, from a blow of the fist. The effused blood generally occurs as an infiltration being more or less widely diffused through the connective tissue, where it is speedily brought

under the influence of the absorbents, and in a very short time completely removed, a few days often sufficing for the purpose. What is called an *ecchymosis* so often found in contusions, consists essentially in a slight extravasation of blood, caused generally by the rupture of the smaller vessels, situated in the connective tissue, immediately beneath the skin, and presenting itself in the form of a livid, black, deep blue, or purple spot, of irregular shape and variable size. It generally comes on immediately or within a short time after the infliction of the injury, and is usually superficial, although it may be deep-seated, affecting the interior of a muscle, a bone, or a viscus. Numerous ecchymoses are occasionally found in the brain, lung, spleen, and liver, after accidents, in which the parenchymatous structure of these organs has been more or less severely bruised. When, in consequence of an injury, the blood is collected in a small circumscribed spot, the affection takes the name of " thrombus," while the term " depot" is employed to designate it when it is large and concentrated. The accumulations of blood which occur on the child's head, and in the labium of the mother, during severe and protracted labor, are good illustrations of a sanguineous depot, so often met with upon a large scale in severe contusions, both with and without any external wound. When the extravasation is copious, it is presumable, whatever may be its form, that it has been caused by the rupture of some of the larger vessels, and such an occurrence should, therefore, always be regarded as one of a serious character, often placing limb and life in jeopardy.

The presence of blood in the contused structures, whether occurring as an ecchymosis, a thrombus, or a depot, is denoted by discoloration of the skin, and by a marked sense of fluctuation, some parts of the swelling, however, generally feeling harder than others, depending upon the manner in which the blood is bound down by the overlying tissues. When an artery of considerable size has been laid open, there will be, in addition to these phenomena, more or less pulsation and murmur, or that peculiar whirring sound so characteristic of aneurism.

The extravasated blood, in contusions, may be perfectly fluid, semifluid, or solid, the consistence depending upon the amount of injury sustained by the parts. When the injury has been very severe, the blood may be completely devitalized, and then it will of course be perfectly fluid, as, for example, not unfrequently happens in the accumulations that occur upon the child's head in difficult and protracted labor; very generally, however, it is partially, if not completely, coagulated, and it need hardly be added, what indeed is self-evident, that the condition of the blood greatly influences its own ultimate disposition, as well as the effects induced by it upon the tissues in which it is located. When it retains its vitality, and the quantity is inconsiderable, it is usually speedily absorbed, or, even if it remain for some time, it is not likely to excite any mischief. When, on the contrary, the blood is necrosed, it is either not absorbed, or it is soon decomposed and thus becomes a source of irritation and inflammation, leading, not unfrequently, to suppuration, ulceration, or even mortification, the more especially if the soft parts have been much contused, or if they are severely compressed by the extravasated fluid. When the blood is very abundant, it may, even if it retain its vitality, so oppress and choke the absorbent vessels as to incapacitate them for its removal, just as sometimes happens in large dropsical effusions. Occasionally the blood separates into its two constituent elements of serum and crassamentum. The opinion that this fluid, in favorable conditions of the part and system, may become vascularized, and gradually transformed into connective tissue, is generally admitted by pathologists, although such an occurrence must necessarily be uncommon and exceptional. Whether the new growth, as it may under such circumstances be regarded, occasionally forms the starting-point of various kinds of tumors, innocent and malignant, is not determined, greatly as the question has been agitated.

The more severe forms of contusion are occasionally followed by more or less effusion of pure serum, unaccompanied, apparently, by any fibrin and hematin. The occurrence is most common in injuries in which the skin is forcibly torn from the subcutaneous connective tissue, especially when it is detached obliquely, as when the wheel of a carriage passes over a limb, severely bruising the soft structures without causing an open wound. The ruptured capillary vessels in such a condition readily part with their serous contents, while the more solid portions of the blood are retained, the quantity poured out varying from a few drachms to several ounces. The ordinary site of the effusion is the subcutaneous connective tissue, but, at times, it is also found in the intermuscular. The fluid appears either as a circumscribed, globular tumor, soft and fluctuating, or, as is more commonly the case, as a veritable extravasation, vague, undefined, and undistinguishable from an ordinary accumulation of blood under the skin, excepting that there is, perhaps, less

discoloration of the surface. In chronic cases, the fluid is sometimes distinctly encysted. In its color the fluid, at first, is generally somewhat reddish, but it gradually assumes a pale amber hue, and eventually becomes perfectly clear and limpid ; it is viscid to the touch, saline in taste, and coagulable by heat and acids.

A contusion may be dangerous or otherwise, according to its extent, the nature of the parts involved, and the state of the constitution. A slight bruise in a person in ill health at the time of its occurrence, may become a source of great suffering, even when the structures affected are not at all important to life, from the supervention of suppurative inflammation, ulceration, or gangrene. A severe contusion of an internal organ, as the spleen or liver, may prove speedily, if not instantly, fatal. A contusion of the scalp may cause erysipelas, phlebitis, abscess of the brain, pyemia, and death. Old men not unfrequently perish from injuries of this kind inflicted upon the prostate gland in lithotomy and lithotrity. A contusion complicated with the laceration of important vessels and nerves, the crushing of bones, and the perforation of the larger joints, is always a dangerous occurrence. Limb and life are sometimes imperilled secondarily, as when there is a large accumulation of blood, rapidly undergoing devitalization and putrefactive decomposition, poisoning the system by the imbibition of noxious gases and ichorous matter. The prognosis is unfavorable in severe contusions occurring in persons exhausted by scurvy, anemia, typhoid fever, and long-continued and profuse discharges.

In the *treatment* of contusions the leading indications are, to prevent further effusion, to limit inflammation, and to promote the removal of the accumulated blood.

In the lighter forms of injury the application of cold water, simple or medicated, will generally be all that is required for a speedy cure. Lotions of arnica, vinegar, and common salt, lead, Goulard's extract, chloride of ammonium, alum, and spirit of camphor are among the most important agents in this class of injuries, most of them acting as powerful sorbefacients, at the same time that they tend to repress excitement and prevent effusion. Pounded ice, inclosed in a bladder or rubber bag, spread out over the affected surface, is often a very valuable remedy, but is not to be used without proper vigilance, lest it should harm by depressing the vital powers of the part. Leeches may be scattered over the affected surface when there is much local disorder. Cataplasms and warm water-dressing are sometimes serviceable. The most trustworthy sorbefacient is a strong solution of chloride of ammonium, with the addition of a small quantity of vinegar, applied upon folded flannel, covered with oiled silk, and renewed six or eight times in the twenty-four hours. Parts excessively contused generally require stimulating applications, as alcohol and water, or lotions of spirit of camphor, not, of course, too long continued.

When the blood is devitalized, or in a decomposed condition, whether fluid or coagulated, it should be promptly evacuated by a free incision, the abnormal cavity being well washed out immediately after with tepid water, impregnated with permanganate of potassium, or, with a few drops of any of the acids. Undue reaction is controlled with morphia, while the treatment, in other respects, is managed upon general principles. When the cavity left by the discharge of the effused blood is very large, reunion will be promoted by the use of the compress and roller. Diffused aneurism is treated by exposure of the wound, and by the ligation of both ends of the affected artery. Amputation may become necessary when the contusion occupies an extremity, and is attended with extensive pulpification of the soft tissues, crushing of the bones, laceration of important vessels and nerves, and the penetration of the larger joints. The treatment of the secondary effects of contusions will receive proper attention in connection with the diseases and injuries of the different organs and textures.

Cavalry-men and grooms are exposed to a severe form of contusion of the tibia, from the kick of the horse. The accident is liable to be followed by violent inflammation, with a tendency to erysipelas and diffused abscess. Recovery is often slow, and suffering great, especially if there has been much concussion of the bone, or extensive injury of the periosteum. The treatment is conducted upon general principles, with the addition of free incisions to liberate the soft parts, the knife grating against the surface of the bone, as in the operation for whitlow.

Tissues that are firmly compressed, constricted, or strangulated are placed very much in the condition of contused structures, and are liable, if not promptly rescued, to become severely, if not fatally, constricted. A bandage tightly wound around an inflamed limb may give rise to gangrene ; a ring slipped over the wrong finger, to violent inflammation ; and the narrow aperture through which the intestine descends in a recent hernia, to mortification of the protruded structures. Paraphimosis affords a good illustration of the

compression and contusion of a part by the action of the common integument, the effect being similar to that produced by the pressure of a tight ligature. The first effect of such an occurrence is an impediment in the vessels and nerves, interfering with the circulation of the blood and the transmission of nerve fluid, speedily followed by an effusion of serum, giving rise to a soft, glossy, œdematous condition. If prompt relief be not afforded, the obstruction increases, inflammation is set up, lymph is poured out, the circulation is completely suspended, and the parts, assuming a dark, mottled, purplish, or blackish hue, are irretrievably lost. These effects often ensue in an almost incredibly short time, as, for example, is so often witnessed in strangulated hernia, especially in cases of recent standing accompanied with an unusually small aperture of descent.

The treatment of these and similar affections is sufficiently obvious, the first and most important point being the removal of the exciting cause, after which an attempt must be made to repair any damage that may have been done by the constriction, special pains being taken to restore the circulation and to promote the absorption of inflammatory deposits.

SECT. III.—INCISED WOUNDS.

Incised wounds are simple cuts made with any sharp instrument, as a knife, a sword, or an axe, and vary in extent from the slighest possible incision to a gap of frightful length and depth. The largest incised wounds are usually made designedly by the surgeon in the extirpation of tumors, in the amputation of the limbs, and in the resection of the joints. In general, they are open, and therefore in contact with the air; sometimes, however, they are subcutaneous, and therefore exempt from such exposure. All incised wounds, however simple, are characterized by three phenomena, deserving of special consideration : 1st, hemorrhage ; 2dly, more or less pain ; and 3dly, retraction of the edges of the divided structures.

1st. The hemorrhage varies in quantity, from a few drops to several ounces, or even quarts, according to the extent of the injury, and, above all, the vascularity of the affected tissues. When the capillaries alone are involved, the blood oozes rather than flows away, the reverse being the case when a tolerably large vessel is divided. The hemorrhage may be strictly arterial, but generally it is both arterial and venous. In the former case the fluid is of a scarlet color, and spirts out in jets, synchronously with the contraction of the heart ; in the latter, on the contrary, it is of a dark modena, or purple complexion, and issues in a continuous stream, as in bleeding at the arm. Some structures are naturally more vascular than others, and, therefore, yield more blood when divided. Thus, a wound of the lip bleeds more freely than one of the cheek, and of the cheek than one of the leg. Again, a part that is habitually irritated bleeds, when divided, much more copiously than when it is in a healthy state. A familiar example of this occurrence is afforded in excision of the tonsils, an operation which is sometimes attended with profuse hemorrhage, in consequence simply of the enlargement of the vessels, and their inability to retract on account of inflammatory effusions.

2dly. The pain, like the hemorrhage, attendant on an incised wound, is influenced in its extent by the size of the lesion, the nature of the affected textures, and the temperament of the individual. In general, it very soon subsides, and does not afterwards return, unless there is undue inflammatory action. When a large nerve is implicated in the injury, there is usually, in addition, some degree of numbness in the surrounding tissues, and occasionally, also, partial paralysis in the distal parts.

3dly. The retraction of the edges of the wound is dependent upon the natural resiliency of the cutaneous and muscular tissues. It is very materially influenced, however, in its degree, by the depth of the wound, by its situation, and also by the amount of motion to which it may be subjected immediately after the receipt of the injury. Thus, a wound of the hairy scalp, extending down to the bone, will hardly gape any, while one on the forehead, arm, or leg will exhibit a frightful cavity ; in the one in consequence simply of the muscular contraction of the part, and in the other of the change of posture.

The *treatment* of such an injury is perfectly simple. The first object is to arrest the hemorrhage, provided this has not been already done by the natural efforts. When it is strictly capillary, it will either soon cease spontaneously, or it may readily be checked by exposing the wound to the air, or by pressing upon it a sponge wet with hot water. When, on the other hand, it proceeds from a vessel of considerable size, the more prudent course will be at once to apply a ligature ; for, although it may be temporarily arrested, it will be very liable to break out again, if not upon the slightest exertion, at all events,

so soon as reaction is fully established, and it may then become a source of great annoyance both to the patient and to the surgeon.

The hemorrhage having been arrested, all foreign substances, however delicate or minute, must be carefully picked away with the forceps, removed with the fingers, or dislodged with a stream of water, squeezed from a sponge, or thrown upon it from a syringe. The finest hair, if allowed to remain, would act as an irritant, and impede the adhesive process. The same remark is applicable to any blood that may cover the wound or incrust its edges. It is just as necessary to remove this as dirt or any extraneous substance whatever. Even the slightest possible layer of blood is likely to prove a barrier to immediate reunion; for, although this fluid sometimes is unquestionably susceptible of organization, such an event is never expected or wished for under such circumstances. Hence the whole surface of the wound should be thoroughly freed of it, not roughly, of course, but as gently as possible, before an attempt is made to approximate its edges. If the blood is coagulated and adherent, it may readily be detached with the fingers, forceps, or handle of the scalpel. Finally, the circumjacent parts, if covered with hair, are carefully shaved and washed.

The object of these preliminaries is to place the wound in the most favorable condition for union by the first intention, or the establishment of the adhesive process. To insure this, the edges must be carefully approximated in their entire extent, and retained in contact for a certain period, by appropriate means, aided by rest and proper position of the part. If the wound is of small extent, nothing will be required beyond a strip or two of adhesive plaster. If, on the other hand, it is long and deep, it will probably be necessary to use, in addition, a few sutures, if not, also, a compress and bandage.

The wound being dressed, and the parts concerned placed at rest in a relaxed, and, if possible, also, in an elevated position, little remains to be done by the surgeon, except to watch and assist nature in her reparative efforts. Within a short time after the edges of the wound have been approximated, inflammation is set up, speedily followed by an effusion of plasma, not only upon their surface, but also into the surrounding tissues. The interposed layer, perhaps hardly as thick as the most delicate spider's web, soon becomes organized, by an interchange of vessels and nerves between the opposite sides, is converted into connective tissue, and thus forms a bond of union between the divided structures. In the meanwhile the inflammation gradually subsides, the surrounding tissues regain their accustomed functions, and the consolidation is completely established. The resulting cicatrice remains rough for some time, but by degrees it becomes polished, and finally assimilates itself to the natural skin, except that it is whiter, destitute of hair, sebaceous follicles, and sweat glands, and less capable of resisting the effects of disease and injury.

But it is not always that the healing process advances so favorably as it is here described. Very frequently, indeed, it is materially retarded, interrupted, or even entirely subverted. Of the various causes which may contribute to bring about this untoward result, the most common are the presence of foreign matter in the wound, want of accurate apposition, too much motion, improper applications, or undue inflammation, however induced. It is, therefore, the duty of the practitioner not only to attend well to every case of this kind in the first instance, but to watch it most sedulously throughout its entire progress, inciting action when it is deficient, and repressing it when it is too high.

If the symptoms assume an untoward tendency, the adhesive action threatening to pass into the suppurative, the sutures and plasters should immediately be slackened, and water-dressing, either warm or cold, simple or medicated, applied, according to the tolerance of the part and system. In general, simple water will be found to answer better than anything else, and may often be advantageously employed from the very commencement, especially if the wound is very large, in anticipation of inordinate action. The diet, bowels, and secretions must be properly regulated; and, if suppuration be inevitable, the most agreeable and soothing remedy will commonly be a light, emollient cataplasm. Gaping of the wound should be counteracted by the use of adhesive strips, aided by position, and, if necessary, by a few loose stitches and the bandage.

SECT. IV.—SUBCUTANEOUS WOUNDS.

Subcutaneous wounds differ from all other wounds in three important particulars: first, they do not have an exposed surface, or, in other words, the tissues that are involved in them are not laid bare; secondly, they are generally followed by very slight inflammatory action; and, lastly, they heal, for the most part, promptly, by union by the first intention,

the whole process of repair being one of unusual rapidity, evidently due to the fact that no air is admitted into them to embarrass the cure. It is upon a knowledge of these principles that Stromeyer and his followers founded what is now known as subcutaneous surgery, a branch of practice which is of such signal service in the treatment of malformations and deformities.

There are, properly speaking, two varieties of subcutaneous wounds, sufficiently distinct in their character to entitle them to separate consideration. In one, that to which the above remarks are chiefly applicable, the wound communicates with the exterior, the aperture by which this is effected being usually a mere puncture, such, for example, as is made in tenotomy, or in the subcutaneous division of a tendon; in the other, which is often a formidable lesion, the skin is not perforated, and, consequently, there is no admission of air, not even transiently. Such wounds are essentially contused and lacerated wounds, in which, even occasionally when the lesion is of the most formidable character, the integument either retains its integrity, or, as more commonly happens, it is somewhat bruised, cut, or torn, but not completely divided. A simple fracture is essentially a subcutaneous wound of a bone and of the adjacent soft structures. A wound made by the tearing away of a tendon from a muscle, leaving behind its sheath, is a lesion of a similar kind. Thus, it will be perceived that, although in one of these wounds air is admitted, and in the other excluded, yet the former is by far the more simple of the two, seldom much inflamed, and generally easily healed.

The subcutaneous wound most commonly met with is that so often made in tenotomy and in kindred operations practised for the rectification of various affections of the muscles, aponeuroses, ligaments, and other structures, and which, in its character, combines the puncture with the cut. Lesions of this kind have been studied chiefly in connection with tenotomy, and I shall, therefore, limit myself, in great measure, in what I intend to say upon the subject of subcutaneous wounds, to what occurs in a divided tendon.

In tenotomy, the skin, generally pierced somewhat obliquely, is opened just sufficiently to admit of the easy introduction of the knife used for the division of the tendon. The moment this is effected, the ends of the cord acted upon by the muscle with which it is connected retract, thus leaving a gap of variable extent between them. The little puncture in the skin being immediately closed with adhesive plaster, the parts are placed precisely in the same condition as in a wound originally without an external opening. The air that always enters such a wound is speedily absorbed; the effused blood, too, soon disappears, and nature, ever on the alert in such a case, rapidly fills up the gap with plasma. Some inflammation necessarily ensues, but the action is slight, and in no wise hostile to repair, or to the development of new tissue. The plasma, at first soft and jelly-like, and of a ruddy tinge from the intermingling of hematin, the result of the knife's work, gradually augments in firmness, and presently assumes a grayish or whitish appearance. Proliferation and growth are active, but the cells rarely advance beyond the fusiform, and often, at an early period, manifest a retrograde movement, degenerating and atrophying. The surrounding tissues always participate in the inflammatory action, becoming red, injected, slightly swollen, more or less tender, and infiltrated with bloodliquor. The new piece of tendon, when fully developed, is found to bear so close a resemblance to the primitive as to be with difficulty distinguished from it; it fills exactly the original gap, and thus forms a continuous structure, slightly overlapping and ensheathing the retracted extremities, and soldering them firmly together, much after the fashion of the ensheathing callus in a broken bone. As the process approaches completion, the neighboring structures gradually return to their normal condition, their vascularity disappearing, the inflammatory material being cleared away, and eventually function being completely restored.

What occurs in a subcutaneous wound after the division of a tendon happens, under similar circumstances, in other structures; the new connecting bond, however, is not always precisely like the original, especially in muscle and cartilage; and the retraction of the divided ends is generally much less than in tendon. Thus, in the connective and adipose tissues, in nerves, ligaments, and fibrous membranes, it is hardly perceptible unless the parts are forcibly stretched during or immediately after the division.

In the second class of subcutaneous wounds, the risk to limb and life forms in many cases a most important element; for, although there is originally no external opening admitting air, yet the injury inflicted upon the affected tissues is frequently so severe and extensive as to be followed, perhaps, in a very short time, by the most disastrous consequences, death being often caused by shock, gangrene, or diffused suppurative inflammation, blood and solids being alike depressed, if not more or less devitalized. The skin,

without being cut or pierced, is often extensively detached from the connective tissue beneath, and is, therefore, in imminent danger of sloughing from the arrest of its circulation. In their character such wounds are essentially bad forms of contused and lacerated wounds. The more simple forms frequently admit of cure, although the structures concerned in them generally remain long in a weak and crippled condition. The reparative process is similar to that of an incised subcutaneous wound, that is, the effused blood is generally carried away, and the plasma that is poured out serves to connect the ends of the divided structures; all redundant substance eventually disappearing, and the parts, if not too much injured, resuming their normal functions. The reason why a simple fracture heals so much more readily than a compound one is that in the one the air is excluded, and in the other admitted. The treatment of open wounds, of whatever character, is often greatly expedited by the employment of protective measures, not too frequently changed. The much vaunted antiseptic treatment owes, I have no doubt, more of its efficacy to this circumstance than to any special virtue of the antiseptic agents themselves.

The treatment of a subcutaneous wound is generally of the most simple kind, perfect rest and elevation of the affected parts constituting the most important elements of success. If the inflammation threatens to transcend the limit of fibrinous exudation, the case must be met by the application of leeches, medicated lotions, the cold water-dressing, or emollient cataplasms, along with appropriate internal remedies. The treatment of contused and lacerated subcutaneous wounds does not differ from that necessary in open wounds of this character, described in a previous section.

SECT. V.—LACERATED WOUNDS.

A lacerated wound is a lesion in which the tissues, instead of being smoothly divided with a sharp, cutting instrument, are torn rudely and forcibly asunder. The edges are ragged and irregular, there is little pain or hemorrhage, and the surrounding parts, frequently bruised and discolored, are cold and numb. The injury most commonly occurs in factories, grist-mills, and steamboats, from the clothes and limbs being accidentally caught in the machinery. Extensive lacerations are often caused by weapons of war; by the teeth of the inferior animals, as the shark, dog, and bear; by the passage of the wheel of a cart or carriage; and by falls from a considerable height, in which the body strikes against a hard and projecting object, as a stone, post, or railing.

A lacerated wound differs from an incised one, 1st, in the slightness of the attendant pain; 2dly, in its indisposition to bleed; 3dly, in its tendency to suppurate and slough; and, 4thly, in its liability to be followed by erysipelas, septicemia, pyemia, tetanus, and other nervous symptoms.

The pain in lacerated wounds is generally very trifling; indeed, instances are frequently met with in which there is no pain at all, the patient being unconscious not only at the moment, but for some time afterwards, of having received any serious injury. Thus in the case of Wood, the miller, as detailed by Cheselden, the arm was torn off at the shoulder, and yet so slight was the pain that the man was not aware of what had occurred until he observed the limb moving round on the wheel. I have seen instances in which the tendons of the fingers, along with portions of their muscular bellies, were pulled out with such velocity that the patient not only experienced no pain, but was for some time utterly unconscious of the injury. When the lesion is very grave and extensive, as when a limb is suddenly severed from the trunk, the attendant shock must necessarily be so severe as, in great measure, to obliterate all local sensation. Upon the occurrence of reaction, however, the pain is frequently intense.

The absence of hemorrhage in a lacerated wound forms a very striking feature, and is the direct consequence of injury done to the vessels. In an incised wound there is no impediment to the flow of blood, because the vessels are divided evenly; in a lacerated one, on the contrary, they are torn into shreds and fragments, which readily intercept the fluid as it sweeps over them, and thus promote the formation of a coagulum, often extending high up into the tube. The vessels, moreover, are partially paralyzed, from the injury sustained by the nervous filaments of the affected parts; hence they are incapable of contracting upon and propelling their contents. In addition to these circumstances, there is frequently, especially in severe lacerations, excessive prostration of the system, which powerfully contributes to the coagulation of the blood, and to the formation of an internal clot. This indisposition to hemorrhage is often present even when very large vessels are wounded. In the celebrated case of Wood, above alluded to, the arm was torn off along with the scapula, and yet there was no hemorrhage. A number of instances of a similar

kind have been published, among the more remarkable of which are those related by La Motte, Morand, Clough, Mussey, Scarnell, Lizars, Braithwaite, Cooper, King, and Lowe.

Lacerated wounds are frequently deceptive in their appearance, the amount of injury being much greater than the surgeon is at first sight led to suppose. The skin, for example, may be affected very slightly, perhaps, indeed, hardly at all, while the muscles, aponeuroses, vessels, and even the nerves, may be extensively severed, or torn up. In many cases the bones are crushed, large joints laid open, and the soft structures completely pulpified. Hence too much caution cannot be observed in our examinations, as well as in our prognosis.

The *treatment* of a lacerated wound is conducted upon the same general principles as that of an incised one. All extraneous matter is removed, the vessels, if necessary, are tied, the parts are neatly approximated, and every precaution is used to moderate the resulting inflammation. In applying the ligature, a sound portion of artery is selected, otherwise secondary hemorrhage will almost with certainty follow the sloughing process. When the hemorrhage is venous, it may generally be promptly and effectually arrested by a compress and roller, so arranged as not to impede the return of the blood to the heart. All undue constriction must be avoided. Ligation is rarely called for, even when the largest veins are torn across. Although it is not probable, from the ragged character of the wound, that much of it will heal by the adhesive process, it is always best to treat the case with reference to this object. For this purpose the edges, after having been neatly trimmed, are lightly approximated, and maintained by adhesive strips, supported by a bandage; all tension is carefully avoided; and large interspaces are left between the plasters for easy drainage. Sutures may usually be dispensed with, although I have not the same dread of them that some surgeons have; for while I have, in many cases, derived the most signal benefit from their employment, I have never seen them do any harm. Any parts that are completely devitalized may at once be cut away, but as there must generally be some doubt on the subject, it is a good rule to let them alone, and intrust their separation to the efforts of nature; or, at any rate, to wait until it is perfectly certain that they are dead.

To moderate the inflammation, water-dressing is used, either warm or cold, as may best comport with the comfort of the patient. On the appearance of suppuration it may, unless it is acting very kindly, give way to an emollient cataplasm, which, in its turn, is superseded as soon as the granulating process is fairly established, by opiate cerate, or the dilute ointment of nitrate of mercury. If the inflammation run very high, threatening to terminate in gangrene, purgatives and nauseants are freely used, and leeches are applied to the parts immediately around the wound. The lancet is rarely required, except in very robust and plethoric subjects, in whom, under such circumstances, it cannot be resorted to too early or hardly too vigorously. The mercury is frequently indicated at the very commencement of the treatment, on account of the concomitant derangement of the biliary and digestive apparatus, produced by the shock of the injury. It should be administered in moderate doses, either alone or conjointly with opium, Dover's powder, or morphia and antimony. Anodynes must be freely given to allay pain and insure sleep. Much judgment is required not to carry the depletion too far. Due allowance must always be made for the waste which must necessarily attend a wound of this description, as well as for the depression which the system experiences in the first instance, and which often continues to exert its baneful influence for days and weeks together.

Attention was called, in 1874, by Dr. F. H. Hamilton, to the treatment of wounds by immersion in simple warm water; and Dr. David Prince, of Illinois, had previously employed what he calls "perpetual irrigation" with warm water impregnated with $\frac{1}{1000}$ solution of carbolic acid and $\frac{6}{1000}$ of salicylic acid. The treatment is especially commended in lacerated wounds and in wounds attendant upon compound fractures and dislocations; it is generally very soothing in its effects, lessens suppuration, promotes cleanliness, and conduces in many cases, cases even of an apparently desperate nature, to recovery. I have no personal experience with this method of treatment, but have great faith in the judgment of the two able surgeons who so highly recommend it.

Secondary hemorrhage in such a wound may arise as soon as reaction takes place, or it may be postponed until the sloughs begin to separate. In the latter case it will not be likely to occur before the fifth or sixth day. When there is reason to expect such an event, as when an artery of considerable size is implicated, the patient should be most sedulously watched until the crisis is past, a tourniquet being placed loosely around the limb, and the nurse instructed in its use, so as to be fully prepared to meet the emergency

the moment it arises. For the want of such precaution, life might be destroyed in a few minutes, before it is possible for the attendant to reach the bedside.

Tetanus, as the result of a lacerated wound, is most frequently met with in nervous, irritable subjects, during the prevalence of hot, or damp, chilly weather, and often arises without any obvious cause, either as it respects the injured part or the system. Anodynes, especially morphia and chloral in large doses, will sometimes promptly arrest it in its earlier stages, but when fully developed it almost always proves fatal, whatever may be the nature of the treatment.

When the laceration is seated in an extremity and involves important vessels and nerves, or when it is accompanied by a comminuted fracture, a compound dislocation, or a disorganized state of the soft parts, amputation will probably be required, the proper period for its performance being the moment reaction is fully established. If it be undertaken while the patient is pale, faint, and exhausted, he will almost certainly die from the shock of the operation, either immediately, or, at most, within a few hours after. On the other hand, amputation must not be postponed until the system has been assailed by inflammation, since this would equally compromise the result. The time, then, for interfering is when the heart has, in some degree, resumed its wonted action, the pulse reappeared at the wrist, the color returned to the face, and the warmth been reëstablished in the extremities ; then, but not until then, is the use of the knife proper.

SECT. VI.—CONTUSED WOUNDS.

A contused wound derives its chief characteristics from the compressed and disorganized condition of the tissues, and occurs in two varieties of form, the open and the subcutaneous, the integument in the latter retaining its integrity, whereas in the former it is more or less cut or lacerated. The injury, in either event, may arise in a great many ways, as from a blow with a heavy bludgeon, the kick of a horse, the passage of the wheel of a carriage, the contact of a partially spent ball, or the explosion of a gun, shell, or rocket. An ugly contused wound is occasionally received in a high fall, in which the person alights among sharp and disjointed stones, upon a pile of timber, or upon a mass of rubbish. The most severe accident, however, of this kind, is that which follows the passage of the wheel of a railway car, in which the body is most frightfully mangled, the soft parts being literally pulpified and the bones ground in pieces. The contusion and laceration which occur under the scalp during the descent of the child's head in parturition afford a good illustration of a subcutaneous contused wound.

The effects of a contused wound are various. When the injury is very severe, life may be destroyed on the spot, precisely as in a gunshot wound, from shock or loss of blood, without any attempt whatever at reaction. In the milder forms, however, the consequences may be very trifling. From the manner in which the structures are bruised, there is generally but little pain both in the first instance and for some time afterwards ; the part feels merely stiff and numb, perhaps somewhat sore and tender ; by and by, however, when inflammation arises, the pain is often considerable, and in some instances it is even extremely severe. When the injury is extensive, there is always violent shock ; the patient is deadly pale and almost bereft of consciousness, the pulse is hardly perceptible, and there is great coldness of the extremities. When he recovers from this state, he is apt to suffer from vomiting and various nervous disorders. If the weather be hot, or the constitution unusually irritable, he may be seized with locked jaw. Neuralgia is also liable to occur as a sequel of such accidents.

Another peculiarity of the contused wound is the trivial hemorrhage which usually attends it ; resembling, in this particular, the lacerated and punctured wound. The vessels being bruised and paralyzed, are unable to propel their contents, which, consequently, almost instantly coagulate, thus opposing an effectual barrier to the effusion of blood, which is also, at the same time, in many cases, if not generally, deprived of its vitality in the midst of the injured and perhaps pulpified tissues. When, however, the lesion is very slight, the vessel always throws out more or less blood, although the flow is never copious, except when an artery of considerable size has been laid open, when it may be so great as to prove speedily fatal. Much, then, will depend, in every instance, so far as bleeding is concerned, upon the extent and the particular character of the lesion sustained by the coats of the vessels, and also, but in a minor degree, upon the injury inflicted upon the blood itself.

Although there frequently is little or no bleeding in such a wound immediately after its occurrence, there is generally, if the injury be at all extensive, great danger of secondary

hemorrhage.   The period at which this will be most likely to arise is when the sloughs begin to separate, which, on an average, will be from the fifth to the tenth day, according to the size of the breach and the amount of the concomitant contusion.   Hence, as in lacerated and gunshot lesions, the patient should always be diligently watched during this time, lest, hemorrhage coming on unexpectedly, he should perish before proper assistance can be obtained.

Contused wounds seldom heal, even in any considerable degree, by union by the first intention ; the vessels are too much crippled to furnish healthy plasma ; and the inflammation is often so violent that the surgeon is extremely fortunate if he can restrain it within suppurative limits.   Gangrene is by no means uncommon, the more especially if the lesion be at all severe ; for there are few cases in which more or less tissue is not devitalized during the infliction of the injury, and, under such circumstances, more or less sloughing is of course inevitable.   Large abscesses often follow, particularly in contusions of the scalp, the hands and feet, the walls of the abdomen, the perineum, and the muscles of the thigh, back, and shoulders, the matter being not unfrequently extensively diffused among the surrounding structures, and preceded in its development by erysipelatous inflammation, a nervous, irritable, and exhausted state of the system generally powerfully predisposing to the untoward occurrence.

Serious injury is occasionally inflicted upon the trunk or upon a limb, without any outward evidence whatever of the fact, perhaps not even the slightest bruise, scratch, or discoloration of the surface.   Such accidents are most frequently caused by the passage of the wheel of a carriage, the kick of a horse, machinery in rapid motion, or the blow of a cannon ball, and are easily accounted for by the elasticity of the skin, which enables it to glide out of the way of the vulnerating body, while the other and deeper-seated structures, destitute of this property, are sometimes completely destroyed by its contact, the vessels and nerves being cut to pieces, the muscles torn into shreds, the bones crushed, and the largest joints laid open.   The scalp is sometimes extensively detached from the cranium by a fall upon the head, without any external wound, and a partially spent cannon ball, striking the belly obliquely, has been known to tear open the bowels, spleen, and liver, without leaving any mark or trace whatever upon the skin.   Such injuries, which are essentially subcutaneous wounds, are peculiarly severe, and are liable to be followed by the worst consequences ; often proving fatal on the instant, or, subsequently, from the effects of inflammation.

A contused wound occasionally exhibits the appearance of an incised wound.   Such an occurrence may readily arise when the soft parts are struck by a blow, kick, or fall, by which they are brought forcibly in contact with the osseous surface beneath, which thus acts as a resisting, vulnerating agent.   The effect will be more likely to arise if the tissues overlie a sharp ledge or bone.   The rent thus produced may be transverse, oblique, or longitudinal, and of variable width and depth.   The most common sites of such injuries are the face and head ; and an accident as simple as a blow with the fist has been known to occasion them in these regions.   A kick on the vulva, violently compressing this part against the pubic bone, may cause a similar lesion.   A rent, closely resembling an ordinary cut, is sometimes inflicted upon the lip by a front tooth in a blow, fall, or kick upon the mouth.

What is vulgarly called a *brush-burn* is a peculiar form of contused wound, the consideration of which properly falls under the present class of lesions.   It is most commonly met in manufacturing districts, and is generally caused by machinery in rapid motion, or revolving belts and similar contrivances.   It may also be produced by sliding rapidly down a hill or on rough ice.   The immediate effect of such contact is an abrasion of the cutaneous surface, in which the superficial structures of the skin are ground to pieces, at the same time that they are partially burned, while the underlying tissues are more or less bruised and disorganized.   The accident, unless very slight, is generally followed by severe pain and inflammation, occasionally terminating in gangrene.

In the *treatment* of contused wounds the leading indications are to arrest hemorrhage, to limit inflammation, and to promote the absorption of effused fluids.

Hemorrhage is controlled in the usual manner ; by compression, styptics, and hot water, if it be slight or venous ; by ligature, if it be copious and arterial.   When the bleeding vessel is concealed, as when the wound is subcutaneous, it may be extremely difficult to find it, owing to the bruised and infiltrated state of the parts, which often renders the search one of great labor and annoyance ; still, it is the only resource, and, therefore, the sooner the operation is performed the better, for it will certainly not at all

facilitate the undertaking if it be postponed until the supervention of inflammation. If the obstacles are unusually great, or if, in the attempt to tie the artery at the seat of injury, important structures are found to be in the way, it will be well to secure the vessel at some distance above the wound; trusting that any recurrent bleeding that may arise will either cease spontaneously, or yield to systematic and persistent compression.

Although we can hardly expect to obtain much, if any, union by the first intention in a contused wound, no harm can result from trying, as the effort cannot possibly make matters any worse. With this view, the edges of the wound should be as nicely approximated as possible, care being taken, of course, not to draw them together at all tightly; for due allowance must be made for swelling and drainage, which will always be more or less considerable in this class of lesions. No fear need be entertained respecting the use of sutures, provided they are introduced loosely, and not too numerously. I never hesitate to employ them in such cases, for I have never known them to be followed by any ill effects. It is only when they produce tension, or when they are made to embrace improper tissues, that they are likely to prove prejudicial. The same remarks are applicable to adhesive strips; they cannot be dispensed with, but they must be applied with great care, and in such a manner as to leave free room for the escape of fluids. Some authors advise that the edges of the wound should be neatly trimmed prior to their approximation, but such a procedure is never justifiable, unless it is perfectly clear that the tissues are dead, or so ragged and irregular as to render it impossible to effect accurate apposition. It will generally be well to intrust this matter, in great degree, if not entirely, to the operation of nature.

A few sutures and adhesive strips are usually the only dressings required. The parts, having been properly adjusted, are kept constantly wet with evaporating lotions, of which alcohol, largely diluted with water, is generally the best. Weak solutions of acetate of lead or Goulard's extract are also serviceable. Such cases are usually benefited by slightly stimulating applications, as they impart tone to the enfeebled vessels, and thus ward off erysipelas, so frequent in this class of lesions when treated in the ordinary manner. Leeches and iodine may become necessary when the inflammation is very active, and then a poultice will also generally be found to be more grateful than cold water or astringent lotions. The bowels and secretions must receive due attention, but severe purgation, and, in fact, all active depletion must be studiously guarded against. Proper allowance must be made, in every case, for the profuse discharges which are so liable to follow contused wounds. If mortification should occur, the treatment will not differ from that consequent upon ordinary inflammation. Pain and nervous symptoms are controlled by anodynes and antispasmodics. When granulations begin to spring up, the milder ointments will advantageously supersede the warm and cold applications; the former proving now too relaxing, and the latter too repressing.

The removal of extravasated blood is best effected by the tincture of arnica, in the proportion of three ounces to the pint of water, diligently applied with patent lint; and by cold, astringent lotions, such as acetate of lead, Goulard's extract, alum, and chloride of ammonium. After the lapse of a few days, the part may be frequently bathed with spirit of camphor, or soap liniment; painted with dilute tincture of iodine; or covered with a poultice made of crumbs of bread and common salt, or of the bruised roots of briony. Under this treatment an ordinary ecchymosis will often vanish in a few days; in the more severe cases a much longer time may be required.

When the extravasated blood appears as a distinct depot, or as a concentrated collection, attended with marked tension of the integument, the speediest way of getting rid of it is to make a small opening, barely sufficient to permit the blood to drain off, if it be fluid, or to be pressed out, if it be coagulated. The walls of the sac are then approximated by a compress and bandage, and irritation is kept down by the ordinary antiphlogistic means.

The treatment of brush burn is conducted upon general principles; the most soothing application, in the first instance, is a solution of acetate of lead in glycerine, and afterwards, especially if gangrene is threatened, weak lotions of nitric or carbolic acid and a yeast poultice.

SECT. VII.—PUNCTURED WOUNDS.

A punctured wound is a peculiar injury, deriving its name from the nature of the instrument with which it is inflicted, and the manner in which the tissues are divided. It comprehends all those lesions which are produced by nails, splinters of wood, thorns, pins,

needles, pieces of bone, or fragments of glass; or by the thrust of a dirk, bayonet, lance, sword, or any other sharp-pointed weapon. The operation of tapping affords a familiar instance of such a wound. The sting of the bee, wasp, and other insects, and the bite of the snake, dog, rat, and other animals, are all examples of this class of injuries, with this difference, however, that most of them are inoculated with the peculiar poison secreted by these creatures, and hence they naturally come to be considered separately. In common, every-day life, punctured wounds are most frequently met with in the hands and feet of the working classes. In dissecting and sewing up dead bodies the physician often punctures his fingers, and sometimes suffers severely in consequence, apparently, from the introduction of a peculiar septic virus, generated either during the act of dying or shortly after dissolution.

Punctured wounds vary much in extent, direction, and character; thus, they may be superficial or deep, narrow or wide, straight or crooked, simple or complicated: circumstances which must necessarily exert more or less influence upon their prognosis, treatment, and termination. Their depth is usually much greater than their width, and for this reason it is often extremely difficult to determine the amount of injury done to the parts in which they are situated.

A punctured wound is peculiar, not only as it respects the mode of its production, but also in regard to its effects. The tissues are forcibly pressed asunder, and, consequently, more or less contused, if not also a good deal lacerated. The wound made by the bite of a man and the inferior animals is usually both a punctured and a lacerated wound; so also when a splinter of wood, or a similar body, is violently driven into the flesh during an engagement on shipboard, or when a person is suspended by a hook or impaled upon a railing. A needle, nail, or a piece of bone, on the contrary, usually makes a purely punctured wound.

The pain attendant upon such a wound is frequently very excruciating, depending, evidently, not so much upon its extent as upon the injury sustained by the nerves of the part, and the bruised and condensed state of the tissues. Hence the suffering, which is often immediate, is sure to be immensely increased if the resulting inflammation is at all severe. It is always greatest, other things being equal, in persons of a nervous, irritable temperament. Much also will depend, in this respect, upon the nature of the vulnerating body. The puncture, for example, made in the operation of tapping the abdomen with a trocar generally causes very little uneasiness, while that of a nail, penetrating the sole of the foot, deep down among the muscles, usually produces the most intense agony. Violent nervous symptoms often supervene upon such accidents, and in hot climates, as well as in the hot seasons in the colder latitudes, they are liable to be followed by tetanus, especially among negroes and the more intemperate classes of whites. The disastrous effects which even the slightest puncture may occasionally produce, in a person of great susceptibility, is strikingly illustrated in the remarkable case, related by Sir Astley Cooper, of a young lady, who, on being pricked with a sewing needle, screamed, fainted, and died.

Punctured wounds are rarely attended with much hemorrhage, indeed frequently hardly any at all; if a large artery, however, has been penetrated, then the bleeding may not only be copious, but, perhaps, almost instantaneously fatal. The thrust of a sword, lance, dirk, or bayonet into the chest, abdomen, neck, or thigh, often literally taps the vessels, destroying the patient in a few minutes. The shock of such a lesion, too, may prove to be of consequence; even a slight puncture is sometimes followed by excessive prostration, and it has been found that soldiers, during engagements, are seldom able to continue the fight beyond a few minutes after they have been deeply pricked by the point of any of these weapons. The shock is excessive, and the patient soon falls into a fatal syncope.

Another peculiarity of punctured wounds is their liability to be followed by erysipelas, angeioleucitis, abscess, contraction of the limbs, and wasting of the muscles. Mortification will not be likely to ensue unless the main artery or nerve of an extremity has been severed, or the system at the time of the injury is in a bad condition. Punctured wounds of the scalp, hands, feet, and joints, especially the larger, as the knee, ankle, elbow, and wrist, are particularly prone to be followed by severe nervous and inflammatory symptoms, and also by erysipelas, the latter generally coming on within less than thirty hours after the infliction of the injury. When the lymphatic vessels become involved, as they often do, the disease is indicated by red lines, extending from the seat of the injury towards the nearest lymphatic glands. A similar phenomenon, along with more or less induration, is witnessed when the veins participate in the mischief; an occurrence by no means uncommon.

The secondary effects of punctured wounds are often very serious, entailing much suffering, with occasional deformity and loss of limb, and demanding much care on the part of the practitioner. Needles, pins, fragments of glass, and pieces of bone sometimes enter the tendons, ligaments, and aponeuroses, and, causing severe and protracted irritation, ultimately lead to irremediable contraction.

Much of the local distress in punctured wounds arises from the injury done to the nerves, by the partial division of their filaments. The gap thus left is nearly always filled up with hard, callous matter, of a fibrous, or fibroplastic structure, ill adapted for the transmission of nerve fluid, and almost invariably the seat for a long time afterwards of more or less pain and tenderness. Neuralgia is also a common occurrence; and not unfrequently all the muscles in the neighborhood of the affected part are eventually completely atrophied and rendered useless.

The *treatment* of punctured wounds consists, first, in the extraction of the foreign substance, in case it has not been already dislodged; secondly, in checking hemorrhage; and, thirdly, in moderating inflammation and preventing the development of nervous symptoms.

To determine whether any extraneous matter remains in the wound, all that is necessary, in most cases, is simply to inspect the vulnerating body. If this exhibit marks of fracture, the probability is that a part of it has been left behind; if so, the probe and finger will assist in detecting it. Should the wound, however, be very deep and narrow, it may be necessary, before this can be done, to make an incision, the extent of which must depend upon the circumstances of each particular case, the only care to be observed being the avoidance of important structures, especially vessels, nerves, and tendons.

When a needle or other slender substance is imbedded in the flesh, or buried in the connective tissue, its presence may often be detected by folding up the skin over it, or making gentle and systematic pressure with the ends of the forefingers at its supposed site, which is generally indicated, at least in recent cases, by a little puncture, perhaps not as large as a flea-bite, upon the surface. Sometimes the local pain or tenderness affords valuable information as to the precise spot where the needle is lodged. The surgeon should not hesitate, when there is reason to believe that the foreign body is retained, to make a free incision for the purpose of extracting it; it is much better to do this at once than to temporize with the case, or to wait until serious symptoms arise, when such a procedure becomes inevitable, although it may now be too late to prevent altogether its bad effects. I have found after long experience that the best forceps for extracting needles and other sharp-pointed bodies are such as are rather long and slender in the blades, with deeply serrated surfaces. The ordinary dissecting forceps are generally worse than useless, especially when, as often happens, the substance is firmly imbedded. Mr. Marshall, of London, has suggested a very ingenious mode of detecting the fragment of a needle imbedded at some depth. It consists in holding a powerful magnet upon the suspected spot for a quarter of an hour, in order to influence the fragment, when, a finely hung polarized needle being suspended over it, deflection will ensue if iron be present.

In the sole of the foot, pieces of bone, glass, and other small bodies are sometimes buried deeply beneath the plantar aponeurosis, where it is often impossible to determine their presence, however carefully searched for. A case which forcibly illustrates this fact fell under my observation, many years ago, in a boy, nine years old, who was wounded by a piece of chicken bone, nearly an inch long, which entered the sole of the foot, and lodged deeply in the substance of the flexor muscles, in contact with the metatarsal bones. Pain and swelling soon followed, but the boy, despite his suffering, continued to walk about, limping, of course, for upwards of a fortnight; the weather, in the mean time, being excessively hot. Suddenly symptoms of tetanus came on; Professor Willard Parker, then my colleague, and I now saw the case, and, although every effort was made to discover the foreign body, it could not be detected, such was the depth at which it was situated. Death followed in a few days, when the bone was found to be so completely buried as to require a very elaborate dissection to remove it.

Removal of foreign bodies, deeply imbedded in the flesh, will be greatly facilitated if the limb be previously constricted with the elastic roller. All barbed instruments, hooks, and similar substances, should be extracted either by counteropenings, or by pushing them across the part in which they are imbedded. Any attempt to extricate them by pulling at them in the direction in which they entered would only increase the difficulty, unless a very free incision be made over them.

The bleeding in punctured wounds generally ceases spontaneously. If a large artery has been laid open, or divided, it must be exposed, and tied at each extremity, in the usual manner. If this cannot be done, compression may be tried, as in the treatment of aneu-

rism ; or, this failing, or not being deemed admissible, the main trunk of the vessel is tied at some distance from the injury.

To prevent the occurrence of severe pain and nervous distress, a full anodyne should always be given, if the case is at all severe, immediately after the accident, and the part wrapped up in flannel, wrung out of warm water and laudanum and frequently renewed.

If the general health suffer, a dose of calomel should be administered, followed by oil or senna. If fever arise, antimonial and saline preparations with morphia may be required, to act on the skin and bowels, to allay pain, and to induce sleep. If matter form, as indicated by the tension and throbbing of the part, free incisions must be made ; erysipelas, angeioleucitis, and phlebitis being treated in the usual manner. Nervous symptoms are combated with the liberal use of anodynes, bromide of potassium, chloral, and other means.

Along our Indian borders very severe wounds, of a punctured character, or partly punctured and partly incised, are often inflicted with the *arrow*, which, as is well known, is capable of being projected, with extraordinary precision, to a great distance. Being usually made of the young willow, or other suitable wood, it varies in length from two feet to two feet and a half, and is feathered in the greater part of its extent, in order to facilitate its movements and increase its speed through the air. The head is generally furnished with a spear-shaped piece of flint, obsidian, or iron. This, which is technically termed the point of the weapon, is of a flattened conical figure, its length from base to apex ranging from three-quarters of an inch to an inch and a half; the corners, or angles, project in a line with the side of the free extremity, and are usually upwards of an inch in width, the whole arrangement being such as to enable the instrument to operate on the principle of the barb of a fish-hook. Thus constructed, the point is securely fixed in a notch on the head of the arrow by means of the tendinous shreds of the deer, coated with the resin of the fir-tree.

It is supposed that many of our Indian tribes poison their arrows, so as to inflict a more deadly wound; but I am told by a former pupil, Dr. William F. Edgar, that this practice is peculiar to the savages inhabiting the mountainous regions watered by Pitt River, one of the northern branches of the Sacramento. These people, it is said, use the poison of the rattlesnake, by grinding the dried head of that reptile into an impalpable powder, which is then applied by means of the putrid blood and flesh of the dog to the point of the weapon, the wound made by it proving speedily mortal.

Wounds made by arrows often, Dr. T. C. Henry, U. S. A., informs me, partake of the nature of incised wounds, or those inflicted by the thrust of the small sword ; and a similar remark has been made by Dr, J. H. Bill, in an elaborate paper on this class of injuries in the American Journal of the Medical Sciences for October, 1862. The iron heads of these weapons are exceedingly thin, and, when propelled with great force, make a clean cut, a portion of which not unfrequently unites by the first intention. Arrow wounds are often attended with great shock, especially when inflicted upon internal organs, resembling, in this respect, gunshot and similar lesions.

Arrow wounds are frequently complicated with copious hemorrhage, and they are also extremely liable to be followed by profuse suppuration, the matter often burrowing extensively among the muscles and other structures. Erysipelas and pyemia are not uncommon. Arrow wounds of the internal organs, as the lungs, liver, spleen, and intestines, almost invariably prove fatal, especially if the point of the missile, detached from its shaft, is retained among the tissues or lodged in a splanchnic cavity.
Fig. 106.   Fig. 107.

Contrivances for the Extraction of the Point of the Arrow.

In the treatment of arrow wounds, the first indication is to extract the extraneous substance, and then, bleeding having been arrested, to limit the resulting inflammation by appropriate antiphlogistic measures. Long and deep incisions will often be required to effect dislodgment, especially if the arrow is impacted in the head of a bone, or buried at a considerable depth among the muscles and aponeuroses. The best probe for determining

its situation is the finger. Rotating the shaft of the arrow upon its axis, or twisting it between the thumb and forefinger, is a good method for ascertaining whether the point of the weapon lies loosely among the soft structures, or is imbedded more or less firmly in bone. Stout forceps, with long and well-serrated blades, should be employed, and the success of the operation will be greatly increased if care be taken during the manipulation not to detach the shaft from the point of the arrow. The extraction, as stated by Dr. Bill, is sometimes greatly facilitated by means of a noose made of stout annealed wire, passed through a double canula, a Coghill's suture twister, fig. 106, or the contrivance represented in fig. 107, carried around the point of the weapon. If abscesses form, they should be promptly opened, to prevent infiltration and destruction of tissue.

SECT. VIII.—TOOTH WOUNDS.

Wounds inflicted by the bite of the human subject and of the inferior animals, as the dog, cat, or rat, partake of the nature of contused, lacerated, and punctured wounds. Such lesions are by no means uncommon, and, from the danger which so often attends them, are worthy of special consideration. I have met with a number of cases of severe suffering from wounds of the fingers received in the act of striking persons upon the mouth. The inflammation consequent upon such injuries is prone to run into erysipelas, especially if, at the time of the accident, the constitution is in a deranged state, and it is sometimes so violent as to be followed by mortification. In 1851, a distinguished jurist struck a man upon the mouth, wounding his finger slightly against his teeth. Erysipelas speedily supervened, and the hand was obliged to be amputated; subsequently the disease reappeared in the stump, and necessitated the removal of the arm.

A woman, forty-seven years of age, always in good health, scratched the skin slightly over the knuckle of the right index-finger in a blow in which she struck the front tooth of a servant girl; only a few drops of blood were lost, and there was hardly any pain. Within two hours afterwards, however, the part began to ache and throb; the finger swelled rapidly to an enormous degree; the whole limb became enlarged and exquisitely sensitive; and a deep red line extended as high up as the axilla, the lymphatic glands of which were very tumid and tender to the touch. Great constitutional disturbance, attended with loss of sleep and appetite, supervened; and a large abscess formed in the theca of the finger, followed by necrosis of the last phalanx and ankylosis of the other joints. The whole limb remained for a long time sore, tender, and swollen, and upwards of a year elapsed before the reëstablishment of the general health.

A farmer, thirty-six years of age, struck a man upon the mouth, receiving a superficial abrasion over the knuckle of the little finger of the right hand. Violent erysipelas of the whole limb followed; the finger became enormously swollen, and a large abscess formed in it, eventuating in necrosis of the phalanges. The general health suffered greatly, and a fresh attack of erysipelas broke out after the amputation of the finger. Many months elapsed before final recovery occurred.

A physician, upwards of seventy-two years of age, received a small wound upon the left index-finger, in striking a lad upon the front teeth. Erysipelas soon showed itself, attended with exquisite pain, and extending up the limb beyond the elbow. After much suffering, in which the constitution seriously participated, the inflammation, at length, disappeared, leaving the finger stiff, crooked, withered, cold, and benumbed.

A farmer, forty-seven years of age, in good health, in December, 1851, struck a man on his mouth in such a manner as to bring the knuckle of the metacarpal bone of the right ring-finger forcibly in contact with the incisor teeth; the skin was slightly broken, but he experienced no particular inconvenience at the time. The same evening, however, the hand and finger became painful and stiff, and the next day they began to swell and to present an erysipelatous appearance. Excessive suffering ensued, producing profound constitutional disturbance; and finally, in about three weeks, a large abscess formed in the hand, requiring the lancet. When I first saw the case, at the end of this time, the thumb and all the fingers were stiff and immovable; the wrist-joint was also much affected, and, in fact, the whole limb was sore and painful. In August, 1852, the thumb and fingers were still rigid and useless, much colder than natural, numb, and considerably attenuated. Every attempt to bend the fingers was attended with severe suffering. The right ring-finger was ankylosed at the metacarpo-phalangeal joint. There was still much uneasiness in the palm of the hand, and the whole limb was atrophied.

The bite of the human subject is often followed by violent symptoms, coming on soon after the infliction of the injury. A considerable number of such cases have fallen under

my observation, and in several I have experienced much difficulty in saving limb and life. I do not presume that the saliva in this class of wounds has anything to do with the production of the bad effects by which they are so liable to be succeeded; the parts are badly bruised, or bruised, lacerated, and punctured, and it is well known how prone such injuries, however induced, always are to be followed by erysipelas and other serious consequences, especially in persons of intemperate habits or disordered health.

The bite of the inferior animals, particularly if they are much enraged at the time, is often succeeded by a very bad form of erysipelas. Many years ago I attended, along with Dr. Trimble, a child, three years of age, who, a few days previously, had been bitten by a rat in one of his fingers. A severe attack of erysipelas soon came on, involving the whole hand and forearm, and causing most violent local and constitutional suffering. The injured part was converted into a large unhealthy ulcer, discharging a thin, sanious fluid, and was a long time in healing. Recovery finally took place, but not without permanent ankylosis of the finger, and partial atrophy of the hand and forearm. The bite of the dog, cat, horse, mule, ass, and camel frequently occasions violent inflammation and great general disturbance. Prescott Hewett has reported a case in which the bite of a ferret caused pyemia and death. Severe wounds, combining all the unfavorable conditions of punctured, lacerated, and contused wounds, may be inflicted by the claws of the feline races of animals, as the cat, lion, and tiger. The inflammation that follows upon the injury inflicted by the bill of certain birds, as the turkey and duck, is often extremely severe, and even dangerous, cases of gangrene and death having been witnessed from its effects. A fatal wound has sometimes been inflicted by the spur of a cock, and the peck of a hen.

The treatment of tooth wounds and abrasions must be conducted upon the same general principles as that of ordinary contused and punctured wounds. The part, however, should always, as a preliminary measure, be well cleansed and bathed with warm salt water, to rid it of any saliva and any other matter that may have been deposited by the teeth; after this, the best application will be an emollient poultice wet with a solution of acetate of lead and laudanum, followed, if necessary, by leeches, and, if matter form, by early and free incisions. Dilute tincture of iodine, pencilled over the inflamed surface around the wound, will also be useful. The best internal remedies are calomel and opium, with an active purge at the commencement of the treatment. When the case is obstinate, alteratives and tonics with change of air may be required.

SECT. IX.—GUNSHOT WOUNDS.

Gunshot wounds are injuries inflicted by fire-arms, as pistols, muskets, rifles, carbines, cannon, shells, and rockets; and are dangerous or otherwise according to their extent, the nature of the affected structures, and the state of the system at the time of their receipt. Occurring in all parts of the body, they may, in one case, be so slight as hardly to attract serious attention, while in another they may be so severe as to cause death upon the spot, either from shock or loss of blood, or, secondarily, from the violence of the resulting inflammation. Even when the person is so fortunate as to escape with his life, he often remains miserable ever afterwards on account of his mutilated condition, the repeated formation of abscesses, or the occurrence of neuralgic pains, which, hardly leaving him any respite from suffering, keep his mind and body in a state of constant irritation, and thus utterly incapacitate him for enjoyment and usefulness.

The missiles generally employed in civil life, in this country, are pistol, rifle, and musket balls, varying in volume from that of swanshot to that of a small marble. The round bullet, formerly used in our army, has been entirely superseded by what is called the new rifle-musket bullet, on account of its greater efficiency. It is of a cylindro-conoidal shape, with a hollow base and three circular grooves, weighs 500 grains, and penetrates, when impelled by a charge of sixty grains of powder, at a distance of 200 yards, eleven one inch pine planks, placed one inch and a half a part. At the distance of 1000 yards it penetrates three and one-fourth of such planks.

The British, French, and Russians employ a considerable variety of bullets adapted to the peculiarities of their respective services. The Enfield ball, used by the English since 1853, has superseded nearly all other missiles of that description. It is a long conical ball, hollow in the base, and weighs $\mathrecal{3}$j and $\ominus$ij. The Martini-Henry ball weighs about 428 grains. The French Minié ball weighs $\mathrecal{3}$j, $\mathfrak{Z}$ij and $\ominus$ij, and the Russian ball, also conical, weighs $\mathrecal{3}$j and $\mathfrak{Z}$vj. The Chassepot ball is nearly cylindrical, and weighs 380

grains. The Prussian ball is somewhat egg-shaped, weighs 530 grains, inflicts an ugly wound, and frightfully shivers the bones. The ball of the mitrailleuse weighs one ounce and three-quarters; the Austrian ball 400 grains.

It has been found in military operations that the cylindro-conoidal ball, meeting with less resistance from the atmosphere than the round, passes, consequently, to a much greater distance, and does more terrific execution upon entering the body, generally proceeding in a straight line, and fracturing and comminuting the bones in a most frightful manner; thus causing a much greater mortality, as well as a more frequent necessity for amputation. The conical ball, moreover, is less liable to be flattened and divided than the round ball, and the aperture of exit is nearly always opposite to that of entrance, which was not so often the case formerly. Much of the gravity of gunshot wounds of late years has arisen from the substitution of the conical bullet. To show with what force a Minié ball occasionally acts, it may be stated that it has been known to pass through the bodies of two men and to lodge in that of a third standing some distance behind.

Sometimes two balls are united by a bar or chain of iron, and put in a cartridge, thus producing, when fired, a terrible wound, as often happened in the Schleswig-Holstein war. In the naval action off Camperdown, in 1797, great destruction was wrought by the Dutch, by the discharge of bags of nails and pieces of old iron. During the war in the Crimea, the Russians occasionally employed an incendiary ball, consisting of a small cylinder of copper filled with a detonating substance, made up in the form of an ordinary cartridge, and discharged from a musket, the projectile, on striking an object, exploding with violence.

Cannon balls are solid bodies, made of cast-iron, and ranging in caliber from one to many pounds, according to the object which they are designed to accomplish. They are either round, or of a cylindro-conoidal shape, the latter of which possesses the same advantage over the former as the cylindro-conoidal bullet over the spherical. A grape-shot is composed of nine cast-iron balls, disposed in three layers of three balls each. Formerly the shot were confined in a canvas bag, fastened to a wooden spindel with a strong cord, the whole bearing a faint resemblance to a bunch of grapes, whence the name. From this the canister shot differs principally in being contained in a tin cylinder closed at the top and bottom. The balls, arranged in four layers, are packed in sawdust. "Shells are large hollow spheres of iron loaded with gunpowder, which may act either in their entire form as solid balls, or subsequently by the explosion of their contents, and their subdivision into numerous splinters, by which their ravages are greatly extended. Shrapnell shells, so named from their inventor, are hollow spheres, loaded partly with gunpowder, partly with balls."

Slugs and fragments of cannon balls often occasion frightful wounds, lacerating the soft parts, crushing bones, laying open joints, penetrating splanchnic cavities and committing other ravages, either fatal at the moment or proving so by secondary involvement.

A pistol ball. if fired near, inflicts quite as deadly a wound as a musket, carbine, or rifle ball. This missile is now generally of a conical shape, and operates with great effect, both upon the soft and hard structures.

Serious injury, extremely liable to be followed by tetanus, is often inflicted with the toy pistol, as it is termed, in such common use in this country on the fourth of July and during our Christmas holidays. The hands and fingers are the parts usually wounded, and the lesions, even when superficial, are very liable to cause severe nervous symptoms, especially during our hot summer months.

A buck-shot wound is at present of rare occurrence. During our last war with Great Britain it was sufficiently common. Buck-shot are sometimes inclosed in wire cartridges, and are then very effective, carrying close for twenty yards, diverging somewhat at fifty, and entering separately at one hundred and fifty, readily penetrating a yellow pine board an inch thick.

Small *shot*, striking the body in a concentrated form, produce effects similar to those of a large bullet; if they are scattered, the injury will be less grave, unless they happen to hit an important organ, as the heart, brain, or spinal cord, when death may ensue in a few minutes, or, more remotely, from the resulting inflammation, as in several instances that have fallen under my own observation. Lachése ascertained by numerous experiments that a load of small shot discharged at a dead body, at a distance of ten inches, will make a clean, round opening; at from twelve to eighteen inches the opening will be very ragged and irregular; while at thirty-six inches each shot will enter separately.

Grave injury sometimes follows the explosion of a *percussion-cap*. Such accidents are sufficiently common among sportsmen, whose pleasures of the chase are often requited by

the loss of an eye, and by the most excruciating suffering, from the lodgment of a piece of the foreign body in one of the chambers of that organ, or in the substance of the iris, lens, or vitreous humor.

Wadding discharged from an ordinary fowling-piece may occasion a fatal wound, as in an instance which occurred, many years ago, at a Philadelphia theatre where, from this cause, a man lost his life in a sham-fight upon the stage. The wadding—a common cartridge—struck the side of the head, fracturing the temporal bone, and, passing across the brain, lodged against the falx of the dura mater, from which it was extracted after death by Dr. John Rhea Barton. In 1838, a girl was killed in England by the discharge of a gun loaded with paper pellets, some of which penetrated the body and lodged in the lungs and liver. In two other instances life was destroyed by a single pellet; in one, by laying open the fifth intercostal artery, and in the other by breaking the orbital plate of the frontal bone, and injuring the brain. A case is recorded of a man being fatally wounded by a kid-glove with a button attached to it; it was discharged from a blunderbuss loaded with powder, and struck the person, who was standing ten feet off, upon his abdomen, in the cavity of which it was found on dissection.

Powder alone, without any wadding, may, when discharged near the body from a gun, pistol, or fowling-piece, occasion fatal injury. From the experiments of Lachèse it appears that, when the distance does not exceed six inches, and the weapon is large and strongly charged, the wound thus made will bear some resemblance to that produced by a small shot, each particle that escapes combustion acting like a pellet. The fact that the mere explosion of powder near the body is capable of causing severe bruises, contusions, lacerations, and even death, has long been familiar to observers. A remarkable case of the latter occurred in this city in 1847, in a lad, a patient of Dr. Paul Swift. The charge, fired from a pistol, entered the left hip, inflicting a wound four inches in depth by one inch in diameter, blackened throughout by the powder, grains of which adhered to its surface. The integument and muscles were severely torn and discolored. Death occurred on the seventh day from tetanus. The instances are quite numerous of great suffering, mutilation, and disfigurement from the lodgment of grains of powder in the eyes, face, neck, and other parts of the body. Stone-quarriers are particularly liable to such accidents.

In its character, a gunshot wound is a punctured wound, with more or less of the nature of a contused and lacerated wound; at the opening of entrance, and for some distance around, the tissues are bruised, but as the ball passes onward it tears the parts, and at the opening of exit they often look as if they had been cut with a sharp knife. The effects of the transit of the missile upon the soft textures may be explained, as was first suggested by Sir Charles Bell, by a reference to a diagram consisting of three concentric rings, as in fig. 108. The first, including the tubular wound, is bounded by tissues which are so compacted, condensed, or contused as to deprive them partially of their vitality, or, at any rate, to place them in such a condition as inevitably to lead to suppuration; consequently this por-

Fig. 108.

tion of the wound seldom unites by the first intention. The structures between the first and the second rings, having sustained less injury, will also inflame, but only, as a rule, in such a manner as to give rise to a deposit of lymph and pus; while those between the second and third circles will either retain their natural properties, or, becoming excited, will merely experience some slight serous infiltration.

The above phenomena may generally be studied to the greatest advantage in deep flesh wounds, as those of the thigh. In such cases there is often a considerable slough of the bruised tissues, upon the separation of which the parts are seen to suppurate and to form granulations, while farther on they are hard, next œdematous, and beyond this natural. These phenomena, however, do not generally pervade the entire length of the wound; for frequently a considerable portion of the track unites by adhesive action, the tissues being lacerated instead of contused, as they are in the early stage of the passage, and, consequently, favorable to restoration. The precise point where the tubular wound loses the character of a contusion and assumes that of a laceration cannot usually be ascertained, as it must necessarily vary very much in different cases, and under different circumstances.

The preceding remarks in regard to the injury inflicted by the projectile are chiefly applicable to the smaller kinds of balls, such as the pistol and rifle; the larger ones are generally productive of more serious mischief, and hence it often happens that the wound sloughs in its entire length, from the opening of entrance to that of exit; there being afterwards, when the dead parts have separated, extensive and tedious suppuration, the

matter, perhaps, burrowing deeply among the soft structures, and thus greatly retarding the process of repair.

Disposition of the Projectile.—The manner in which the projectile is disposed of varies; sometimes it lodges, and then, of course, it makes but one opening; at other times it passes completely through the part, and so leaves two apertures, one of entrance, the other of exit. Cases occur where one ball may make three, four, or even more holes. Thus, if it encounter a sharp edge of bone, as the crest of the tibia, it may be cut into two or more pieces, each of which may afterwards issue at a separate point. Dupuytren met with an instance in which a ball of this kind made five orifices; and at Antwerp the younger Larrey saw six holes made in a similar manner. Again, a ball piercing the surface, just above the wrist, may be unable to penetrate the aponeurosis of the forearm, but, travelling along for some distance under the integument, may emerge below the elbow; then, the limb being considerably flexed at the moment, it may reënter the skin a second time at the inferior part of the arm, and finally escape near the shoulder-joint; thus leaving four apertures, two of entrance, and two of exit. Such an occurrence is, of course, very rare; but its possibility is worthy of remembrance, as it is of great interest in a medico-legal point of view. A man, for example, might be shot in a duel, and his friends seeing the number of openings in the limb, might accuse his adversary of foul play, on the ground that he had used more than one ball.

A curious case has been related, by Hunter, of a young man who was shot in the abdomen by three bullets discharged simultaneously from the same weapon, with the effect of making only two openings of entrance and two of exit, one of the missiles following closely in the track of one of the others, as was proved by the fact that they all lodged by separate orifices in the wainscot of the apartment where the accident occurred. During the French war in Algeria, a grenadier was pierced in five places, all wounds of entrance, by a single ball, divided into five pieces by first striking a rock, the fragments rebounding at various angles.

A ball striking an extremity may pass not only completely through it, but also through its fellow, thus making four openings; or it may perforate the upper part of the thigh and then pass through the head of the penis, leaving two orifices in the former and two in the latter, as in a case which I saw in the Hospital at Alexandria, under the care of Dr. Sheldon, after the engagement near Centerville, Virginia, in July, 1861; or, finally, it may traverse both buttocks, or it may perforate one and lodge under the integument on the outer side of the other, as in a man who was wounded in the battle of Bull Run.

When there is only one opening, it is natural to conclude that the ball has lodged, and this, as already stated, is usually the fact. Instances, however, occur, although rarely, where the reverse is the case. Thus, a ball has been known to pass some distance into the pectoral muscle, and to be immediately ejected by the recoil of a rib. The knee-joint has occasionally been opened, the ball being supposed to have lodged in the head of the tibia, but upon amputating the limb none was found, although there was but one opening. Lastly, a ball may enter the body, perhaps rather deeply, along with a piece of cloth, upon extracting which the missile may drop out.

Large balls, fragments of shell, pieces of iron, and other substances, occasionally bury themselves deeply among the muscles, where, from the small size of the opening of entrance, they may long remain undiscovered. Larrey extracted a ball, weighing five pounds, from the thigh of a soldier, who had suffered so little inconvenience from it that it had been entirely overlooked by the surgical attendant; and Hennen refers to a still more remarkable instance as having occurred at Seringapatam. At the battle of Fort Donelson, Dr. Henry W. Davis, of Chicago, amputated a thigh, in the muscles of which a shell, weighing twelve pounds, and measuring four inches and a half in diameter, was buried. In a case referred to by Longmore, a grape-shot, weighing one pound and two ounces, remained in the back of the pharynx for three weeks without exciting any suspicion of its presence.

Considerable difference generally exists between the openings of entrance and exit. The former is usually rounded with even or slightly inverted edges, as if the skin had been tucked in a little, and there is frequently more or less of a bluish or blackish discoloration of the adjacent surface, from the contact of burnt powder, deposited upon the ball at the moment of the explosion, and rubbed off as the ball strikes the body. When the discharge takes place within a few feet of the surface, scorched grains of powder often adhere to the skin, or may even be imbedded in its substance. Occasionally the margins of the orifice have a pale, dead-like aspect, or they may be simply of a livid hue, from the effects of contusion. The opening of exit, on the contrary, has generally a slit-like appearance, looking as if it had been made with a sharp knife rather than an obtuse

body; it is free from discoloration, and its edges, instead of being inverted, are turned out. I have met with cases where both openings had an incised appearance, but such a condition is uncommon.

The size of the two openings is variable. The round ball generally makes a larger orifice of entrance than of exit, the reverse being the case with the conical ball. These peculiarities were remarkably apparent in the wounds of the troops after the battle of Bull Run, in July, 1861. I had occasion also to notice the immense size of the openings in gunshot wounds of the integuments, made by the conical ball, especially when the two apertures were close together. In nearly all the cases of this class of lesions that I observed during the war, the holes, particularly that of exit, were disproportionately large, as well as remarkably irregular and ragged.

Experiments performed by Dr. Sarazin, of Strasbourg, upon the dead subject, with the Chassepot rifle, show that the size of the orifice of entrance is essentially the same as that of the projectile itself, whereas the diameter of the orifice of exit is enormous, being from seven to thirteen times larger than that of the ball.

Shell wounds, and wounds inflicted with stones, nails, splinters, and similar missiles, always exhibit a lacerated appearance, owing to the irregular shape of the vulnerating body. A similar character is often imparted by flattened bullets, and by bullets entering the surface flatwise, as occasionally happens when their course is changed by some intervening object.

When any doubt exists in regard to the nature of the two holes, it may often be promptly dispelled by a careful examination of the openings in the patient's clothing, as here the aperture of exit is invariably the larger and more ragged of the two.

Wounds inflicted by the explosion of torpedoes are usually attended with excessive laceration and contusion of the soft parts. Dr. S. W. Gross, who saw a number of wounds of this kind during our late war, found that grave and deep-seated injuries occasionally occurred without any apparent lesion of the skin, and that very generally they caused complicated fractures, or even carried away portions of a limb; in either event demanding amputation.

A ball in rapid motion, under the impulse of a strong charge of powder, flies like an arrow; it does not revolve on its axis, and, consequently, on reaching the body, it passes through in a straight line, dividing everything before it, and perhaps issuing at a point directly opposite to that of its entrance. If, on the other hand, its force is partially spent, it will either not enter at all, or, if it enter, it will be turned out of its course, the slightest resistance, as that offered by a tendon, ligament, or aponeurosis, serving to change its direction. The circumstances which tend to weaken the force of a ball are two, the attraction of the earth and the resistance of the atmosphere. A strong wind blowing perpendicularly to the direction of the American rifle-musket ball, will deflect it from its course twelve feet in 1000 yards, about one-fourth that distance in 500 yards, and about six inches in 200 yards. Besides, its impulse may receive a serious check by coming in contact with the person's accoutrements or some article of dress, as a button, buckle, or breast-plate, or any substance that may, at the moment, happen to be in his pocket, as a key, pencil, knife, watch, or coin. If, from these, or any other causes, the force of the projectile is partially spent, it may, on reaching the surface, either glance off, or, if it enter, it will be likely to be deflected, the course which it then sometimes pursues being very remarkable. Thus, a ball has been known to pierce the forehead, but instead of penetrating the frontal bone, it passed round the skull, underneath the scalp, and lodged upon the occiput, at a point nearly opposite to that of entrance; or, what is still more extraordinary, it travelled nearly completely round the head, issuing only a short distance from the place where it struck. In the same manner a ball has been found to describe the circumference of the chest, its course being marked by a reddish weal or zone. Cases are mentioned by military surgeons in which the missile, piercing the wall of the chest by the side of the sternum, made the circuit of the thoracic cavity by passing between the costal and pulmonary pleuræ, and either falling down upon the diaphragm, or lodging in the wall of the chest behind, without inflicting the slightest injury upon the lung. Examples of a similar kind occasionally occur in the abdomen, the ball, after piercing the skin, being deflected by the tendon of the external oblique muscle, so as to cause it to course round the belly beneath the integument, and effect a lodgment near the spine, or, perhaps, emerge somewhere upon the back. Finally, cases are not wanting, although they are rare, where the missile entered the abdomen in front, and issued behind, in a straight line, without wounding any of the viscera. Such occurrences find their counter-

part in sword, bayonet, and dagger wounds of the abdomen, in which the walls of that cavity are sometimes completely transfixed, and yet its contents escape unharmed.

A case has been related by Dr. William H. Herring, in which a musket ball, entering the upper and back part of the neck, was discharged at the end of five months by the anus, having, as was supposed, passed by ulceration into the pharynx and thence into the stomach.

When soldiers lie on the abdomen with the head towards the enemy, the ball may pass vertically through the skull, and either lodge or emerge at a distant part of the body. An instance occurred during the war in the Crimea, in which a ball, entering the top of the cranium, traversed the neck, back, buttock, and thigh, and escaped near the knee.

A long bone is occasionally terribly shattered and comminuted by a bullet without the destruction of its continuity, some of the splinters being forcibly driven into the medullary canal, where they are retained, and act as foreign bodies, keeping up inflammation and discharge for an indefinite period. Hennen long ago called attention to this lesion, of which numerous cases occurred during our late war.

Different tissues possess the faculty of deflecting balls in different degrees. Thus bone offers a greater amount of resistance than cartilage, cartilage than tendon, tendon than aponeurosis, and aponeurosis than muscle. Arteries often escape in a remarkable manner, their astonishing elasticity enabling them to glide away from the flying projectile. Common integument, too, readily throws a partially spent ball out of the straight line. Deflection of every description, however, is much less frequent now than formerly, owing to the substitution of the conical for the round ball, the former readily penetrating everything, even when fired at a great distance, whereas the latter is easily spent, and arrested on coming in contact with the more resisting tissues.

A ball, upon meeting a sharp bone, as the crest of the tibia, is sometimes cut in two as smoothly and evenly as if it had been divided with a knife. A gentleman was shot in a street rencontre, the ball striking the clavicle, which split it into two nearly equal portions, one bounding off and escaping, the other lodging in the lower part of the neck, from which I removed it several months afterwards. Cases have occurred in which, as before stated, bullets have been cut into a number of pieces, each perhaps making a separate orifice in the skin. The conical ball suffers much less frequently in this manner than the round.

When a ball strikes a bone, it may be arrested in its substance, or it may perforate it, lodge in the soft parts, or make its escape. In the latter event, the opening of entrance in the bone will generally be somewhat round, and comparatively small, whereas that of egress will be large, ragged, and irregular, with everted edges. The old round ball, in its transit through a bone, often made a hole much bigger than itself, especially if its force was partially spent. Indeed, cases were occasionally observed in which the opening was so capacious as to admit not only the ball, but also the barrel of the weapon from which it was discharged. The conical ball, although it makes a comparatively small aperture of entrance, commits much greater havoc than the round, owing to the manner in which it breaks and comminutes the osseous tissue, the loose splinters themselves thus often becoming a source of severe injury to the soft structures, contusing and lacerating them in every direction.

Grave injury is sometimes inflicted upon a bone, even without the occurrence of fracture, simply from the violence of the shock which it experiences. The bullet strikes its surface with great force, bruising the periosteum, and causing dreadful concussion of the osseous tissue, but the force with which it is impelled is not sufficient to enable it to effect penetration. In such a case erysipelatous inflammation is very liable to be followed by exhausting suppuration, and, perhaps, sloughing and death.

Immense damage is sometimes sustained by the soft parts, by fragments of bone being forcibly driven into their substance, sometimes at a great distance from the site of the original injury. A case occurred in the Crimea, in which a piece of the lower jaw was detected behind the right clavicle; and Professor Hamilton mentions an instance in which, during the late war, a ball and four incisor teeth were removed from beneath the skin at the top of the sternum. In gunshot wounds of the extremities, splinters of bone often do more mischief than the missile by which they are inflicted.

The older writers on military surgery speculated a great deal respecting what used to be called the windage of a ball. It is well known that the most horrible injuries may be inflicted upon the body by shell and round shot, completely pulpifying the muscles, lacerating the vessels and nerves, laying open large joints, and literally crushing the bones, and yet, perhaps, hardly bruise the skin, much less produce any serious wound. The

true cause of these injuries is the manner in which the projectile strikes the surface.   As before stated, a ball in rapid motion will, on reaching the body, pass through it in a straight line ; or, instead of this, it will, if large, as in the case of a cannon ball, carry away the part completely.   But it is very different when the missile is projected lazily, or when, from the great distance over which it has travelled, its force is measurably exhausted. Then the slightest resistance will tend to deflect it, or change its course ; it no longer passes in a straight line, but rolls or turns upon its axis after the manner of a billiard ball ; and hence if, while in this condition, it strikes the body, it may inflict the most frightful injury upon the muscles, bones, and even the viscera, and yet not perhaps leave a trace of its effects upon the skin, the elasticity of which enables it to slide out of harm's way, while the other and deeper structures, which possess this property in a less degree or not at all, readily yield to its influence, and suffer severely in consequence.   In such an event, the patient may instantly perish from the violence of the shock ; or, if he sur- vive the immediate effects of the injury, his life will be likely to be assailed by wide- spread sloughing of the soft parts.

During naval and military engagements, soldiers often have pieces of their dress, accoutrements, and even of their persons, carried away by balls in rapid motion, without sustaining any serious injury in the bones and muscles.   The faculty possessed by the integuments of gliding out of the way of mischief is well exemplified in railway acci- dents, which strongly resemble those inflicted by partially spent round shot, and in which they frequently escape in the most astonishing manner, while the deeper parts, soft as well as hard, are frightfully torn and pulpified.   These gunshot lesions are much less frequent now than formerly, owing to the general use of the conical ball, which does its work more neatly and effectually, as well as at a much greater distance, than the old round ball.

The distribution of wounds during a battle will necessarily vary with circumstances. In an engagement in the open field, the chances are that nearly all parts will suffer alike. In nearly four hundred cases of gunshot injury which I saw after the battle of Bull Run, in July, 1861, almost all the wounds were situated in the extremities, and in nearly equal proportion in the upper and lower.   A few only of the patients had been struck on the head, chest, back, or abdomen.   This cannot, however, be taken as a fair criterion of the result of the engagement, since those that were most severely wounded fell into the hands of the enemy.   At the capture of Fort Donaldson, in February, 1861, accord- ing to the estimate of Dr. Andrews, seventeen per cent. of those wounded were shot in the head and face.   At the battle of Pittsburg Landing, at Fair Oaks, and several other places, the majority of the injuries in the Federal troops were situated in the lower ex- tremities.   According to Hennen, of the wounds received in battle, ten will be in the upper extremity, seven in the lower extremity, seven in the head, four in the neck and chest, and two in the abdomen.   Scrive, from his observations in the Crimean war, con- cludes that, in the open field, one-tenth of the wounds will be in the head, one-twentieth in the chest, and one-fortieth in the abdomen.   Men fired at behind breastworks are most liable to suffer in the head, neck, chest, shoulders, and arms, the lower parts being protected by the defences.

Symptoms.—The symptoms of gunshot wounds necessarily resolve themselves into local and general, or into such as are peculiar to the part and to the system; and, it need hardly be added, vary greatly in their character, according to the extent of the lesion, the importance of the tissues involved, and the idiosyncrasy and other circumstances of the individual.

The pain in a wound of this kind is often very insignificant, the person, although perhaps severely hurt, not being conscious of having received any injury until some minutes after it has been inflicted.   It is generally of a dead, heavy character, altogether different from the pain of an incised or punctured wound ; it is only when a large nerve has been partially cut across that it is likely to be at all severe, and then it is usually very sharp, pricking, or burning.   In this case, too, there will also be more or less numbness in the part below the wound, and sometimes, as when the principal nerve has been entirely severed, complete paralysis.   Thus, in gunshot wounds of the thigh, involv- ing the division of the sciatic nerve, there is always loss of motion, and often, also, of sensation of the knee, leg, and foot, which feel as if they were cold and dead.   The suf- fering is generally great when a bone is broken, a large joint penetrated, or a visceral cavity laid open, and the shock is then also much more severe and protracted.   The pain, however slight at the moment of the injury, is always more or less aggravated upon the supervention of inflammation.

The hemorrhage in gunshot wounds is generally not at all in proportion to the severity of the injury, owing to the contused and lacerated nature of the lesion. The structures immediately around the track of the ball are usually so much condensed that, unless the divided vessels are large, or numerous, the bleeding will, in the majority of instances, be so slight as to excite little, if any, alarm for the patient's safety. Very frequently, indeed, it amounts to the merest oozing, which soon ceases spontaneously, or under the application of cold water. If a large artery, however, has been laid open, the hemorrhage may not only be copious, but so great as to prove speedily fatal, perhaps, indeed, in a few minutes at furthest. Such an event will be more likely to occur if, as so often happens in this class of injuries, the vessel is only partially divided, so as to prevent its retraction; when this is the case the blood will flow most freely, and, although it may be temporarily arrested by syncope, the clot will be washed away the moment reaction takes place, the fainting recurring again and again until the patient has bled to death. If, on the other hand, the artery is completely severed, there may hardly be any hemorrhage whatever until the occurrence of reaction; perhaps not even until the separation of the sloughs.

During a battle it often happens that an extremity, torn off by a shell or round shot, is left hanging merely by the integuments, and yet the patient is in no immediate danger from hemorrhage, the vessels, from their lacerated and contused condition, being instantly closed by coagula.

A ball may pass directly in the course of a large artery, perhaps the main trunk of a limb, and yet the vessel escape injury, or, at most, be merely grazed. The reason of this is the resilient power of the vessel, which enables it to jump, as it were, out of the way of the projectile. Such an artery, however, will be particularly liable to gangrene, and, therefore, to secondary hemorrhage during the separation of the sloughs.

The hemorrhage is generally external, the blood issuing at both orifices of the wound. The reverse, however, may be the case, especially if the injured parts have been thrown out of their relative positions, or if, as sometimes happens, there has been extensive separation of the muscles; in such an event a large quantity of blood may be effused among the deep-seated structures, with hardly any outward bleeding. In wounds of the chest, abdomen, and pelvis, the hemorrhage is usually internal, and therefore the more dangerous, because concealed.

Gunshot wounds are, for the reasons already mentioned, extremely liable to secondary hemorrhage. A large artery may have been merely grazed, and, inflaming, a slough may form, which, separating, may, in a few minutes, give rise to severe, if not fatal, bleeding. Or an artery, of considerable size, may have been completely severed, but its ends, as well as the surrounding parts, having been violently contused, a clot is instantly formed, which thus affords a temporary barrier to the escape of blood; by and by, however, reaction takes place, and then perhaps the artery is reopened, its contents now gushing out in a full stream; or the event may not take place for some days, perhaps not until after the establishment of suppuration, ulceration, or gangrene and sloughing. Sometimes the injured vessel is completely blocked up by the ball or other foreign substance, upon the removal of which copious hemorrhage ensues.

Secondary hemorrhage, the result of sloughing, usually arises from the tenth to the fifteenth day; much, however, will depend, in this respect, upon the size of the ball and the amount of injury sustained by the soft parts around the wound, as well as by the vessel itself. In some instances it does not appear before the twentieth, twenty-fifth, or thirtieth day; and, on the other hand, it occasionally occurs as early as the fifth, sixth, or seventh.

The occurrence of aneurism, as an effect of gunshot wounds, is uncommon, especially the circumscribed variety. The diffused form is more frequent, and is generally a very grave affection, liable to be followed by violent local and constitutional suffering. Sometimes the passage of a ball leads to the formation of an arterio-venous aneurism, as in a number of instances under my observation, one, among others, of which was kindly brought to my Clinic by Dr. W. B. Atkinson, of this city.

The constitutional symptoms are subject to much diversity. The shock is sometimes severe in a degree altogether disproportionate to the violence of the injury; the stoutest and most courageous individual will often swoon from the most insignificant wound, and, on the other hand, a man may have his limb completely shattered, and yet not evince any serious alarm; his mind is perfectly calm and collected, and he is, perhaps, able to give the word of command or cheer on his comrades up to the very moment of his dissolution. Temperament and idiosyncrasy have much to do in the production of these phenomena, and should have due weight in the prognosis of the case. It is said that veterans upon

the field of battle generally, other things being equal, suffer much less apprehension and alarm from their injuries than raw and inexperienced troops.

The subjoined case affords a good example of the manner in which shock occasionally causes death in gunshot wounds in civil life :—An army officer in 1851 fell in a duel, the ball, a very large, round one, fired from a rifle at a distance of forty yards, entered the left thigh a little above its upper third, lacerating the soft parts in the most horrible manner, laying open the femoral vein, and crushing the bone into numberless fragments. The missile then passed into the right thigh, where it lodged, producing, however, but little mischief. Although hardly a pint of blood was lost, the system never rallied, notwithstanding the free use of brandy and other stimulants, up to the moment of the patient's death, two hours after the rencontre.

The shock in gunshot injuries is generally most intense when the ball traverses the head, chest, abdomen, or pelvis, when it splits, breaks, and comminutes a large bone, or when it lays open an important joint, as that of the knee or hip. A wound inflicted with a conical ball is, other things being equal, attended with more collapse than one made with the common round ball. During the Crimean war upwards of two hundred soldiers perished from shock alone within forty-eight hours after the receipt of their injuries.

Great mental agitation, sometimes followed by furious delirium, and even by insanity, has been known to ensue, within a short time after a severe battle, in soldiers who escaped all bodily injury, but experienced excessive alarm and shock the moment they reflected upon the dangers through which they had passed. A number of such cases occurred during the war in the Crimea.

It has generally been supposed that gunshot wounds are peculiarly liable to be followed by tetanus, but this is the case only when the sufferers are neglected, or permitted to lie upon damp, cold ground, or in currents of cold air, after an engagement. When they are properly cared for, the danger from this source is very trifling. Thus, after the affair in Paris, in July, 1830, of three hundred and ninety wounded received into the Hôtel-Dieu, of that city, only one was attacked with tetanus. In the Peninsular war the proportion was estimated at about one in two hundred ; and in the Schleswig-Holstein campaigns, according to Stromeyer, at one in three hundred and fifty. In the English army in the Crimea, the number was exceedingly small, being only 0.2 per cent. of the wounded ; and the French loss, during the same period, did not exceed altogether thirty cases. After the battle of Solferino, three deaths occurred from this disease, caused chiefly, as is supposed by Bertherand, by the damp, chilly air of the churches in which the wounded were temporarily accommodated. Baron Larrey was struck with the great frequency of tetanus in Egypt, especially in the neighborhood of the Nile and the sea. The mortality from tetanus after naval engagements is sometimes very great. Thus, after Admiral Rodney's action, twenty out of eight hundred and ten wounded were attacked with this disease ; and during our war with Great Britain the proportion was still more frightful. Injuries inflicted upon the hand and fingers by the toy pistol are a frequent source of tetanus. In Baltimore, in 1881, nearly twenty persons, chiefly boys, died from lesions of this kind inflicted during the Fourth of July celebration.

Prognosis.—The prognosis of gunshot wounds varies with so many circumstances as to admit of being pointed out only in a very general manner. Some of the milder cases of this class of injuries often recover promptly, without a solitary untoward symptom, the parts occasionally uniting, as I have myself seen in several instances, by the first intention. In other cases, on the contrary, apparently of a mild character, severe nervous symptoms may arise, or the wound may take on erysipelas, or a bad form of inflammation, and the patient lose his life. In 1857, I attended a young man who had been shot with a pistol, the ball, a small one, having entered the outer and back part of the arm, just above the middle, grazing the humerus, and lodging immediately under the integument, from which I removed it an hour afterwards. The ordinary treatment was employed ; but in thirty-six hours violent erysipelas set in, and death occurred in less than eight days from the time of the injury. On the other hand, apparently the most desperate cases will sometimes recover. Much will, of course, depend, in every instance, upon the size and situation of the wound, the presence or absence of complications, the state of the patient's constitution, the condition of the atmosphere, and the nature of the treatment. Wounds inflicted in battle are generally more fatal than those received in civil life, especially if treated in crowded, ill-ventilated hospitals. Death then often occurs from sheer neglect, or the want of good nursing and suitable surgical treatment.

Some gunshot wounds must necessarily be fatal, either instantaneously, as when they involve a large vessel, or an important organ, or, more or less remotely, as a consequence

of inflammation, gangrene, pyemia, or profuse and exhausting discharge. The danger to limb, if not to life, will be great when a large joint has been laid open, the main artery, vein, or nerve severed, the bone crushed, or the integument extensively stripped off; or when all, or nearly all, of these parts suffer together. Gunshot wounds of the lower extremity are, other things being equal, more dangerous than those of the upper, sharing, in this respect, the same fate as ordinary lacerated and contused wounds.

The causes of death in gunshot wounds are, shock, hemorrhage, pyemia, erysipelas, gangrene, tetanus, profuse suppuration, and hectic irritation.

Remote Effects.—The remote effects of gunshot wounds are often very troublesome, entailing much suffering, and being occasionally followed by loss of life at the distance of many years. In a case of gunshot injury of the chest, related by Dr. M. H. Houston, of Virginia, a thick linen patch, with which the ball had been enveloped, remained in the left lung for twenty years, when the patient died in a state of extreme marasmus, his general health having never been good since the occurrence of the accident. Sometimes a bullet lodges in the head of a bone, where, although it may for a while be comparatively harmless, it ultimately causes necrosis, with inflammation and discharge in the soft parts, thus necessitating the removal of both substances, if not of the limb itself. Marshal Moncey died from the effects of a gunshot wound forty years after its receipt.

In 1861, I removed from the lower part of the leg of a man seventy-nine years of age, shot at the battle of Moscow, a ball weighing six drachms and a half; it was incased in a mass of calcareous matter, and, although it was somewhat rough on the surface, it had remained in a quiet state for forty-nine years, when it gave rise to inflammation, followed by some pain and profuse discharge, necessitating surgical interference. An old soldier, wounded at the battle of Chippawa, carried a half ounce bullet in the upper part of his thigh for sixty-one years. During all this time, however, he suffered more or less from pain and suppuration.

On the other hand, a ball may occasionally remain in the body for a long time, perhaps even in an organ of vital importance, without inducing any particular mischief. Thus, in a case reported by Dr. Henry Wurtz, of New York, an ounce bullet was found, on dissection, in the middle lobe of the right lung, of an old soldier, forty-five years after its introduction at the siege of Badajos. It was inclosed in a distinct cyst, an inch below the surface of the organ, having entered between the fourth and fifth ribs, as was proved by the existence there of an old cicatrice. An Englishman lived, without any inconvenience, with a ball in his back between his shoulders for fifty-six years. Dr. S. W. Gross has recorded the case of a soldier, struck at the battle of Shiloh, in which a cylindro-conoidal ball was encysted in the right cavernous body of the penis.

In gunshot injuries, attended with fracture, it is not uncommon for the wound, after having become apparently perfectly solidified, to reopen, and take on unhealthy action. The cause of this occurrence is usually some foreign substance, generally a piece of dead bone, imprisoned by callus, which, for a time, masks its presence, but does not ultimately prevent it from exciting inflammation and suppuration. More frequently the wound, under such circumstances, remains fistulous until the source of the irritation is completely removed.

Among the more serious remote effects of this class of injuries are, atrophy of the affected limbs, paralysis, either partial or complete, permanent ankylosis, and contraction of the tendons, muscles, and aponeuroses, leading to deformity and loss of function.

Treatment.—In the treatment of gunshot wounds six distinct indications are presented: 1st. To revive the patient, or promote reaction; 2dly. To arrest hemorrhage; 3dly. To ascertain the precise condition of the soft parts and bones; 4thly. To extract the ball and any other foreign matter that may have entered along with it; 5thly. To remove any loose pieces of bone; and 6thly. To circumscribe the resulting inflammation.

1st. *Shock* is relieved by the employment of the ordinary restoratives. If the patient be faint, he must at once be placed in the recumbent posture, with his head as low as the rest of his body; cold water must be dashed upon the face, the fan freely used, and the smelling-bottle passed under the nose. If the symptoms are urgent, sinapisms are applied to the chest, spine, and extremities, a stimulating injection is thrown into the bowel, and, if the power of deglutition is not gone, brandy, wine, or ammonia is given by the mouth. If, however, there is internal hemorrhage, care is taken to bring up the pulse slowly and gently, allowing time for the formation of coagula, and guarding against the occurrence of violent inflammation. A kind look, or a soothing expression, will often do more to revive the patient and encourage recovery than anything else.

2dly. If the *hemorrhage* be capillary, or caused by the division of very small vessels,

it will probably soon cease of its own accord, or simply by exposure of the part to the cold air, or under the application of cold water, pounded ice, or some astringent lotion. If it be venous, compression may perhaps suffice; whereas if it proceed from a large artery, such as the radial or tibial, the only reliable remedy is the ligature. The case is very simple when the vessel is superficial, and the wound capacious; but, under opposite circumstances, the duty of the surgeon is often exceedingly embarrassing. Here it becomes necessary either to dilate the wound, so as to expose the artery and tie it at both ends, which is by far the best plan; or, when this is impracticable on account of the depth of the vessel, its proximity to important structures, or the great swelling and infiltration of the parts, as may happen when some time has elapsed since the receipt of the injury, to cut down upon the main trunk of the vessel, and to secure it as in the Hunterian operation for aneurism. The latter procedure, however, will rarely succeed, inasmuch as the bleeding is extremely liable to be kept up by the recurrent circulation; for this reason it is always best, if practicable, to expose the injured artery at once, and to apply a ligature to each extremity, which cannot fail to put an effectual stop to the flow of blood. The more promptly the operation is performed the better; if the surgeon wait till inflammation has supervened, great difficulty will be experienced, not only in securing the artery, but also in inducing the ligature to maintain its hold upon its softened and partially disorganized tissues. When the hemorrhage has been very profuse, but has gradually or suddenly stopped, it will hardly be safe to intrust the case to the efforts of nature, because, when reaction occurs, the vessel will almost be sure to be reopened, and thus the bleeding may progress until the system is completely exhausted; whereas, if the surgeon has done his duty, the parts will be placed in the best possible condition for speedy recovery. The proper plan in such cases is to do whatever may be necessary without temporizing.

When secondary hemorrhage is expected, as when a ball has passed in the direction of a large artery, the patient should be most sedulously watched until all danger is over. A tourniquet should be placed loosely round the affected limb, and instructions given to tighten it the moment bleeding appears. Meanwhile the patient should be kept perfectly quiet, and everything done to control vascular excitement. If the wound is not too large, it may, as an additional precaution, be plugged with lint soaked in Pagliari's styptic or in a strong solution of subsulphate of iron.

Aneurism caused by gunshot injury must be treated in the same manner as in ordinary cases of this disease; if possible, by ligation of the affected vessel; if this fail, and the symptoms are urgent, by amputation.

3dly. To ascertain the *condition of the wound* is a matter of the first importance, and yet it is one which, I am convinced from much personal observation, is often most grossly neglected. The object should be not only to determine whether there is any foreign substance, but what the actual condition of the soft parts and bones is; whether, in a word, excessive and irreparable injury has been inflicted, forbidding all attempts at surgical interference, whether primary amputation is demanded, or whether the treatment should be wholly conservative. For the want of this precaution many limbs and lives are lost, simply because what should be done at once, at the earliest possible moment, is postponed until it is too late to be of any benefit. Many of the men that are sent from the battle-field to the hospital fall victims to erysipelas, pyemia, gangrene, and secondary hemorrhage in consequence of the irritation produced by retained splinters of bone, shreds of clothing, or other hurtful matter that should have been extracted on the spot. Such neglect, whether caused by ignorance, carelessness, or timidity, cannot be too pointedly condemned, or too severely censured. It need hardly be added that, inasmuch as all explorations of this kind must be painful, the patient should always be thoroughly anæsthetized. Moreover, they should be instituted at the earliest possible moment, before the parts are invaded by inflammation and swelling, as they may then be conducted with comparative ease, and without any serious ulterior harm.

4thly. The fourth indication is the *extraction* of the ball; but to do this it is necessary, in the first place, to ascertain where it is; to grope about in the wound without any definite idea as to its precise location, would only be to inflict additional pain and injury. In order to conduct the examination with the greatest advantage, the part should be put as

Fig. 109.

Author's Bullet Probe.

nearly as possible in the position in which it was at the time of the accident. This is the more necessary, because, as was before stated, the missile often pursues a very different route from what might be supposed from merely looking at the orifice of entrance or exit ; the slightest resistance may change its direction, and cause it to lodge at a point far beyond what it would have sought, had it been permitted to pass in a straight line. Hence attention to the position of the part is, in all cases, a matter of the greatest importance.

Fig. 110.

Sir Charles Bell's Bullet Probe.

In searching for the ball, care must be taken not to mistake for it some osseous prominence. Stromeyer refers to two cases in which he saw this blunder committed : in one the surgeon cut down upon the head of the fibula, in the other upon a metatarsal bone. The assertion of a patient that the ball has dropped out is seldom reliable, unless the missile is found in his pocket.

The course of a ball is sometimes indicated by the impression made by it upon the nerves of the part. Thus, as observed by Sir Charles Bell, when the missile has traversed the pelvis or shoulder, the defect of feeling in the extremity, studied anatomically, will afford useful information in regard to its passage ; whether, for example, it has cut, or is pressing upon, a particular trunk. The color of the blood will indicate whether an artery or vein has been wounded, and the size of the stream whether the vessel is small or large.

The best probe for conducting the examination is the finger, provided it is sufficiently long and slender ; it possesses the same value, in such cases, as direct auscultation in the exploration of the chest, or the finger in the examination of the uterus and rectum, and should, therefore, always be used when practicable. If the digit is inadequate, recourse is had to a stout probe, fig. 109, or fig. 110, from ten to twelve inches in length, as thick as a medium-sized bougie, slightly flexible, blunt-pointed, and composed either of silver or brass. The ordinary pocket probe is much too small. When a suitable instrument is not at hand, the necessary exploration may be performed with a female sound or catheter, or even with a long, slender pair of bullet forceps. The instrument, whatever it may be, is passed along the track of the wound with all possible care and gentleness, otherwise it will be very likely to make a false passage in the surrounding connective tissue, or become entangled among the muscles, tendons, nerves, or vessels. The contact of the probe with the ball usually produces a sensation of roughness and resistance, together with a dull noise if the instrument be struck against the foreign body by short jerks.

When it is doubtful whether the missile has really lodged, or when the missile is retained, but cannot be distinguished from bone, Nélaton's probe, consisting of a metallic rod, the extremity of which is tipped with a small olive-shaped piece of white, unpolished porcelain, capable, when rubbed against a bullet, of receiving a stain from it, will afford the most satisfactory result. The instrument being withdrawn, any blood or pus that may have collected upon its bulb should be washed off with a stream of water, in order that the stain, if any exist, may be brought into full view. When such a probe is not at hand, a good substitute will be found, as suggested by Dr. Gelisch, of California, in one constructed of white pine wood, the extremity of which readily receives the stain of the lead.

Attempts have been made from time to time to detect the presence of bullets by the use of the electric bell-probe, but in hardly a solitary instance with satisfactory results. What future investigations may accomplish in this direction remains to be determined.

Finally, the missile may sometimes be detected with the exploring needle, after all the more ordinary means have failed. The instrument, which should be long, straight, and slender, should be inserted at the supposed situation of the foreign body, and moved about in different directions until the diagnosis is clearly established. The peculiar shape of the missile, and the facility with which it may be displaced, provided it is not firmly imbedded, may be regarded almost as certain indications of its presence.

The bullet being found, the forceps take the place of the probe, the blades being firmly closed as they pass along the track until the point comes in contact with the extraneous substance, which is then seized and extracted in such a manner as not to include any of the surrounding tissues. Occasionally the operator will derive important aid in his manipulations from counter-pressure, the hand or the thumb and a few fingers being applied to the opposite side of the wounded parts.

Bullet-forceps and extractors, of various forms and sizes, are in use. The most important qualities of such instruments are lightness, strength, and slenderness, with length of blade, which should not be less than four inches. The extremity should be well rounded

Fig. 111.   Fig. 112.   Fig. 113.   Fig. 114.   Fig. 115.
Thomassin's Forceps.   Gemrig's Forceps.   Fenestrated Forceps.   Bullet Extractor.   Thomassin's Extractor.

off, and fashioned in such a manner as to adapt itself readily to the shape of the foreign body, and at the same time grasp it with great firmness, without the risk of including any of the adjacent structures. The old forceps did good service during the reign of the round ball, but will hardly answer for the extraction of the conical. For the latter purpose, Mr. Tiemann, of New York, has reintroduced to the notice of the profession the ingenious instrument, fig. 111, devised by Thomassin in the latter part of the last century. It is quite slender in the blade, and is provided with short, stout teeth, projecting somewhat like the incisors of a mouse, their object being to take a firm hold upon any part of the bullet by partially burying themselves in its substance.

Thomassin's instrument has been greatly improved by Mr. Gemrig, by making the end of one blade cup-shaped, with two curved prongs, separated in front by a narrow interval, and terminating each in a point. The other blade has only one prong, also curved, but central, and terminating in a point, which, when the forceps are shut, is received in the interval here alluded to, thus rendering its extremity perfectly blunt. The instrument, represented in fig. 112, answers for the round as well as the conical ball, and possesses the great advantage of facility of application with firmness of grasp.

The forceps delineated in fig. 113 were made in 1861 at my suggestion, by Mr. Gemrig. They are about nine inches and a half in length, light, slender and fenestrated at the extremity, which is scooped out in such a manner as to embrace the ball with great facility, while its inner surface, roughened like that of a stirrup, maintains its hold with extraordinary firmness.

When the wound is unusually large, and the ball not deeply seated, the extraction may sometimes be effected with a small lithotomy scoop, the common dressing or polyp forceps,

or an instrument like that sketched in fig. 114, made for me by Mr. Kolbe. It consists of a silver tube, inclosing a steel stylet, terminating in two blades, cup-shaped on the inside, and movable by a hinge. The extremity of the instrument is seen grasping the ball. Fig. 115 represents a similar instrument, devised by Thomassin, and used by the French and British surgeons. When the course of the ball is very circuitous, or when the missile is imbedded among swollen and infiltrated tissues, advantage may be derived from the elastic forceps of Dr. Weisse, delineated in fig. 116.

Fig. 116.

The gimlet-like instrument, so much extolled by the older surgeons, is now almost obsolete, although it might still occasionally be employed with advantage when the extraneous substance is lodged in a bone thickly covered by muscles. The trephine, however, is generally preferred under this and similar circumstances.

The extraction of a ball and other foreign matter is sometimes greatly facilitated by the elastic roller, or the ordinary bandage, tightly applied. It is especially valuable when the wound is situated among very vascular structures, or when deep incisions are required for the detection or removal of the missile.

A ball, after having traversed the thickness of a limb, or of the body, occasionally lodges immediately beneath the skin or among the superficial muscles, where its presence may readily be detected by the probe or finger. In such a case it should be removed by a *counter-opening*, made by cutting down upon it at the nearest point; a procedure which often saves an immense amount of pain and trouble.

When the ball cannot be found without much probing, and the risk of inflicting serious additional mischief, the best plan is to let it alone, in the hope that it may either become encysted, or that it may be detached and washed away by the discharges. In general, however, every justifiable effort should be made to remove it, on the ground that, if left, it will be almost sure to excite violent inflammation, followed by profuse suppuration and extensive separation of the tissues. Such an event will be more likely to occur when the ball has become rough, jagged, or flattened by striking against a bone; for then it must necessarily keep up irritation so long as it remains, as there is no possibility of its being isolated by an adventitious membrane.

The great importance of not permitting balls to remain unextracted has been placed in a very forcible light by the observations of Hutin, chief surgeon of the Hôtel des Invalides of Paris. Of 4000 soldiers whom he examined, within a space of five years, only 12 had experienced no inconvenience from the retention of foreign bodies, while the rest, 200 in number, had all suffered more or less severely until they were relieved by operation.

Another reason for the early extraction of the missile is that persons soon after the receipt of the injury, generally, submit much more readily to the necessary operation than after they have partially recovered from its effects; their dread usually increases in proportion as they get well, and thus pass beyond the reach of immediate danger.

Weisse's Elastic Forceps.

When a ball lies loose in a movable joint, it should always be promptly extracted; if, on the other hand, it is lodged in an adjoining bone, the proper plan is to let it remain, in the hope that it may soon be covered with plastic matter, and thus become comparatively harmless. The only exception to this rule is where the ball projects into the cavity of the articulation, when it should be removed at all hazards, inasmuch as its retention would inevitably lead to violent, if not fatal, inflammation, and utter uselessness of the part.

No sensible surgeon ever thinks of searching for a ball in any of the great cavities of the body; such a procedure would be sure greatly to increase the dangers of the accident, and cannot, therefore, be too pointedly condemned.

If it be necessary to the welfare of the part and system to remove a ball, which is a comparatively innocuous substance, it is much more important to extract the various *foreign bodies* which so often enter along with it, and the presence of which, however protracted, must be a source of incessant irritation and annoyance. The rule here is imperative, and applies to the smallest as well as to the largest substance ; to the little piece of wadding and the stoutest splinter, the linen shred and the brass button ; in short, to every description of extraneous matter. Wherever it may be, it must be sought for, and, if possible, extracted without delay. There is no chance here for the formation of a cyst, as sometimes happens with a ball ; nature admits of no such liberty. In naval and military engagements large pieces of wood, metal, and other substances are liable to be impelled into the body, in which they are often buried at a great depth, or lodged among the muscles, which sometimes close over them in a sort of valve-like manner, rendering it extremely difficult not merely to extract but even to find them. Much may be done in such cases by the gentle use of the finger and probe, aided by counter-pressure.

5thly. Any detached *splinters* of bone, or pieces of bone so much loosened as to render it improbable that, if left, they will reunite, should be removed as early as possible after the occurrence of the accident, experience having shown that their retention is always productive of extensive and protracted suppuration, if not of worse results. By the timely extraction of such bodies, immense suffering may be prevented, and ultimate recovery greatly expedited. It is surprising that surgeons should ever hesitate in such a case, and yet the instances are not uncommon of the most culpable neglect. A remarkable example of this kind fell under my notice in 1847, in Lieut. George Adams, of the United States Marine Corps, who was desperately wounded in the right thigh by a large musket ball, at the battle of the National Bridge, during our war with Mexico. The soft parts were extensively injured, and the bone shattered into numerous fragments, not less than twenty-four of which, some of them upwards of an inch and a half in length, I removed nine months afterwards, from the enormous callus that had formed around the seat of the fracture : most of them were completely imprisoned in the new osseous matter, and, therefore, very difficult of extraction. The incisions healed kindly, except at one point, which refused to close, owing to the presence of a small piece of bone, which was subsequently removed by the late Professor Warren, of Boston.

When *powder* is imbedded in the skin, every particle should immediately be picked out with a cataract needle, or a delicate bistoury, entirely regardless of pain. Unless this be done, the powder will speedily excite inflammation, besides causing disagreeable and permanent disfigurement by the bluish spots which it will leave. The operation is not only tedious, but always attended with severe suffering. The resulting inflammation is to be combated in the usual manner ; cold water, or cold saturnine lotions, being generally the best local remedies.

6thly. The last indication is to circumscribe and moderate *inflammation*. To fulfil this, attention to various points is necessary. In the first place, the parts must be properly dressed. The rule formerly laid down was that the orifices of the wound should be lightly covered with lint and adhesive plaster. Such a procedure is exceedingly irrational, inasmuch as its direct effect must inevitably be to aggravate the local mischief by interfering with the discharges, of which there will necessarily always be more or less. Instead of this, the orifices should be left open, while, by means of a light compress and bandage, an attempt is made to approximate the sides of the wound in order to promote their reunion. The roller, extending from the distal portion of the limb beyond the seat of injury, must be applied in such a manner as not to impede drainage. By such treatment the cure will often be immensely expedited ; the resulting inflammation will be comparatively slight, infiltration of fluids will, in great degree, be avoided, and suffering will be vastly abridged. The bandage, however, must be used with great caution, for there is danger, especially when there is much swelling, of its producing injurious compression, and thus becoming a cause of gangrene. In gunshot wounds of the extremities, involving the deep muscles and aponeuroses, great advantage will accrue, during the progress of the treatment, from the use of the bandage in preventing the formation of sinuses and in favoring the escape of pus.

The part having been dressed, and placed at rest in an easy, elevated position, cold water is applied, provided there is no contraindication to its use, on account of the state of the weather or the intolerance of the part and system. If the weather be mild, and the patient young and robust, cold will usually be borne better than warmth, and the most eligible form is that of water, either simple, or medicated with opium and acetate of lead. The use of cold water in the treatment of this class of lesions dates as far back as

the time of Biondo, towards the middle of the sixteenth century, and its beneficial effects, although lost sight of for a long time, were again brought prominently before the notice of the profession by Kern, Larrey, Guthrie, and other army surgeons, during the continental wars of Europe early in the present century. Cold water, however, is not tolerated equally well by all patients, and the rule, therefore, is, when it disagrees, to substitute warm applications, either in the form simply of tepid water, or in that of a light, emollient cataplasm, which, after all, makes, in many cases, an admirable dressing, soothing pain, and promoting discharge.

Although water-dressing usually answers a most excellent purpose in this and other classes of wounds, I am certain, from long experience, that its efficacy may generally be very greatly increased by the addition of acetate of lead and opium, the astringent and anodyne effects of which are thus directly imparted to the affected structures. An ounce of the former of these articles with a drachm of the latter to a half gallon of boiling water are the proportions which I commonly employ. The application is made either tepid, cool, or cold, as may be most agreeable to the patient. During my connection with the George Street Military Hospital of this city I had ample opportunities of testing this mode of practice, and of satisfying myself of its superiority.

When much contusion exists, as is so often the case in shell and cannon wounds, the best local remedy is some spirituous lotion, as, for example, two parts of alcohol or tincture of arnica to ten of water, with the addition, if there be any offensive discharge of a small quantity of chlorinated sodium. The tissues, deprived of nervous power, must be slightly stimulated, to prevent them from running into profuse suppuration, if not gangrene.

If the inflammation assumes a threatening aspect, as when it is of an erysipelatous character, and is attended with great pain, tension, and swelling, free incisions, and sometimes counter-openings, must be made, otherwise extensive mischief may result from the burrowing of fluids, and the consequent destruction of the connective tissues. Besides, the parts, if not promptly relieved, might mortify. The older surgeons made it a rule to dilate all wounds of this kind as soon as possible after their infliction, with a view of preventing these and other untoward results, but this procedure has become obsolete, the modern practitioner resorting to it only when the necessity arises on account of the severity of the inflamation; assuming that a man ought not to be cut merely because he has been shot.

When there is profuse suppuration, with extensive separation of the tissues, the wound should be freely syringed several times daily with tepid water, slightly medicated with chlorinated sodium, permanganate of potassium, bromine, carbolic acid, nitric acid, or subsulphate of iron, the latter being particularly serviceable when there is a disposition to bleeding. Much may frequently be done in this manner, not only in preventing the lodgment and burrowing of pus, but in getting rid of any clots of blood, shreds of cloth, or detached splinters of bone that may be present.

The orifices of the wound will usually begin to granulate in from four to eight days, even when there is slight gangrene of their edges, and the whole track will often close in an almost incredibly short time. Much of it, especially if it be long, will be in the condition of a subcutaneous wound, and, therefore, highly favorable to repair. When the passage is slow in filling up, the healing process may be expedited by the use of slightly stimulating injections, thrown in twice in the twenty-four hours; few cases, however, will demand such interference. The wound of exit generally heals first, provided it is not ragged, contused, or interfered with by the discharges.

Conjoined with these local measures must be perfect rest of mind and body, along with a generous diet, gentle laxatives, and anodynes, the latter being given for the double purpose of allaying pain and spasm, and inducing sleep. Opiates are generally borne in large doses, and can rarely be dispensed with in any case, however mild. If the wound is severe, and especially if it be attended with serious hemorrhage, antimonials and active purgation must be scrupulously abstained from, on account of their depressing effects, and their tendency to provoke pyemia and erysipelas. Due allowance must be made, in every instance, for the discharges which are likely to attend such injuries. Hence much judgment is often required to steer clear of difficulty and danger. Bleeding by the lancet is hardly to be thought of under any circumstances; in young and plethoric subjects, however, blood may occasionally be advantageously taken by leeches. In ordinary cases, the diet should be plain and simple, rigid abstinence not being required, except when there is unusual fulness of habit. Marked exhaustion, whether from shock, loss of blood,

inflammatory disturbance, or profuse suppuration, must be met by the use of milk punch, quinine, iron, cod-liver oil, and nutritious food.

If any tendency to erysipelas, pyemia, or hospital gangrene arises, the patient in addition to the means already indicated, should be promptly placed under the influence of iron and quinine along with brandy and nutritious food; and if large numbers of wounded are crowded together, no time should be lost in effecting their sequestration.

The progress of gunshot wounds is often seriously interrupted by the occurrence of diarrhœa and dysentery, especially in tropical regions or in the heat of summer, among troops that have been exposed to malarious influences. The discharges rapidly reduce the strength, and often, in the course of a very few hours, completely arrest the granulating process. The best remedies are quinine and iron in union with opium and arsenic. Powdered charcoal and permanganate of potassium are also valuable remedies, either alone or variously combined with other articles, particularly anodynes. A scorbutic state of the system is best rectified with subacid fruits and vegetables, tonics, beef essence, and milk punch. In all cases the patient should have the full benefit of fresh air, frequent ablutions, and change of clothing.

When the cicatrization of a gunshot wound is fully completed, there is commonly a marked difference between the scar at the opening of entrance and that of exit. The former is generally somewhat depressed, whereas the latter is either on a level with the adjacent surface or projects very slightly beyond it.

QUESTION OF AMPUTATION IN WOUNDS.

The most horrible wounds are generally those which are inflicted by machinery in rapid motion, the passage of a railway car or the wheel of a heavy wagon, and the explosion of fire-arms, violently lacerating and contusing the soft parts, extensively crushing the bones, and perhaps opening one or more of the larger joints. In many cases, the character and extent of the mischief are apparent at first sight; in others, as when it is principally subcutaneous, it becomes so only after a most patient and thorough examination. The latter class of injuries is particularly to be dreaded, as it is often impossible, even with the greatest care, to determine the extent of the lesion. When the examination necessary to ascertain the condition of the parts is likely to be painful or protracted, commiseration for the sufferer always dictates the propriety of administering chloroform, although the anæsthesia will rarely be required to be carried to the extent of complete unconsciousness, a few full and prolonged whiffs being generally sufficient to effect the desired tolerance.

In attempting to determine the question as to whether an effort should be made to cut off or save a limb, not a little stress should be laid upon the age, habits, and previous health of the patient, the manner in which the injury was inflicted, and the number, variety, and importance of the structures involved.

Young adults bear severe accidents much better, other things being equal, than the two extremes of life, childhood and decrepitude, in both of which, but especially the latter, the power of reaction is generally very feeble, and the effect of shock and hemorrhage felt for a long time. Nevertheless, there is not a practitioner of any experience who has not occasionally witnessed striking exceptions even under these circumstances. A temperate man usually bears up under a severe wound much better than a dissipated one, and the resident of the country than the inhabitant of the crowded city; a person in ill health at the time of the accident will be likely to suffer more than one in an opposite condition. The worst class of accidents in civil practice are those inflicted by railway cars, steamboats, and steam factories, and these are often of such a nature as to require the prompt removal of the mangled and mutilated structures.

But of all the circumstances influencing the recovery of the patient, and the ability of the surgeon to save the mutilated parts, the most important, by far, is the extent of the injury, or the number and nature of the tissues involved. To place this subject in a clear and tangible light, it must be considered somewhat in detail; but, before doing so, it is proper to observe that amputation should never be performed in wounds of any kind until reaction has taken place, for, if this precaution be neglected, the additional shock which the operation would necessarily impart to the system might prove fatal, either before the patient is removed from the table, or soon after. As long as he is deadly pale, the pulse small and thready, the surface cold, and the thirst, restlessness, and jactitation

excessive, the employment of the knife is wholly out of the question. The proper treatment is recumbency, with mild stimulants, sinapisms to the extremities, and other means suited to reëxcite the action of the heart and brain. Power being restored, the operation is at once proceeded with, due regard being had to the prevention of shock and hemorrhage, the two things now mainly to be dreaded.

The advantages of primary over secondary amputation, in all severe wounds, are too obvious to require comment. Mr. Guthrie long ago ascertained that the loss after secondary operations, in gunshot injuries, was at least three times as great as after primary, and the results of his observations have been amply confirmed by the more recent experience of military surgeons. In the Crimean war, where the wounds were, for the most part, inflicted with the conical ball instead of the round, as in the cases seen by Mr. Guthrie, the difference was less marked, but still strikingly in favor of primary interference. Thus, the mortality in 690 primary amputations was 175, or in the ratio of 25.3 per cent., and 38 in 89 secondary, or in the ratio of 42.7. Intermediary amputations are, as will be explained in the chapter on amputations, of all operations of this kind the very worst.

The following circumstances may be enumerated as justifying, if not imperatively demanding, amputation in cases of wounds, of whatever nature :—

1st. When a limb has been run over by a heavy cart, crushing the bones, and tearing open the soft parts, amputation should, as a general rule, be performed, even when the injury done to the skin and vessels is apparently very slight, experience having shown that such accidents seldom do well if an attempt is made to save the limb, the patient soon dying of erysipelas, gangrene, pyemia, or typhoid irritation. The danger of an unfavorable termination is always greater in the lower than in the superior extremity.

2d. No attempt should be made to save a limb when, in addition to serious injury inflicted upon the integument, muscles, or bones, its principal artery, vein, or nerve has been extensively lacerated, or violently contused, as the result will be likely to be gangrene, followed by death.

3d. A lacerated, punctured, or gunshot wound penetrating a large joint, as that of the knee or ankle, and accompanied by comminuted fracture, or extensive mischief of the ligaments, will, if left to itself, be extremely liable to terminate in tetanus, mortification, or pyemia, and is, therefore, as a rule, a proper case for early amputation.

4th. Gunshot wounds attended with severe comminution of the bones, the fragments being sent widely around among the soft parts, lacerating and bruising them severely, generally require amputation, especially in naval and military practice. Gunshot fracture of the thigh-bone is generally considered by military surgeons as a sufficient cause for primary amputation. The rule, however, admits of many exceptions.

5th. Extensive laceration, contusion, and stripping off of the integument, conjoined with fracture, dislocation, or compression and pulpification of the muscles, generally demand the removal of a limb.

In all severe lacerated and contused wounds, whether induced by cannon shot, falls, blows, machinery in rapid motion, or the passage of the wheel of a wagon, the limb should generally be amputated at a considerable distance above the apparent seat of the injury. If this precaution be neglected, mortification will be liable to seize upon the stump, owing to the fact that, in such cases, the injury, both of the soft and hard parts, usually extends much further than the naked eye can discover.

Should amputation be performed when a limb, the subject of a severe wound, laceration, or contusion, has been suddenly seized with mortification, manifesting a rapidly spreading tendency, extending, perhaps in a few hours, up as far as the middle of the leg, or even as high as the knee? Such cases are generally desperate; no local or internal remedies can arrest the morbid action; the system has sustained a profound shock, and the affected parts perish, not by inches, but literally by feet. I have repeatedly seen this variety of gangrene extend from the toes, instep, or ankle as far as the hip-joint in less than thirty-six hours, in cases where there was but little visible injury, the mischief being evidently deep-seated, involving muscle, nerve, vessel, and bone. If amputation is not performed, the disease, the march of which is indicated by a bluish, purple, or livid, crepitating, and tender streak along the limb, will be sure to terminate fatally in a few days, and the operation should, therefore, be resorted to at the earliest possible moment, the surgeon not waiting for a line of demarcation, which cannot take place, since neither the part nor the system has the power of arresting the morbid action. The event, it is true, will generally be unfavorable, but as it is the only chance the patient has, he should,

slender though it be, undoubtedly have the benefit of it.   In the cases in which I have amputated under these unpropitious circumstances, the result in all except three was fatal.

Lacerated, contused, and gunshot wounds are often of so frightful a nature as to render it certain, even at a glance, that the limb will be obliged to be sacrificed in order to afford the patient a better chance for preserving his life.   At other times, the injury, although severe, may yet, apparently, not be so desperate as to preclude, in the opinion of the practitioner, the possibility of saving the parts, or, at all events, the propriety of making an attempt to that effect.   The cases which may reasonably require and those which may not require interference with the knife are not always so clearly and distinctly defined as not to give rise, in very many instances, to the most serious and unpleasant apprehension, lest we should be guilty, on the one hand, of the sin of commission, and, on the other, of that of omission; or, in other and more comprehensive terms, that, while the surgeon endeavors to avoid Scylla, he may not unwittingly run into Charybdis, mutilating a limb that might have been saved, and endangering life by the retention of one that should have been promptly amputated.   It is not every man, however large his skill and experience, that is always able to satisfy himself, even after the most profound deliberation, what line of conduct should be pursued in these trying circumstances; hence the safest plan for him generally is to procure the best counsel that the emergencies of the case may admit of. But, in doing this, he must be careful to guard against procrastination; the case must be met promptly and courageously; delay even of a few hours may be fatal, or, at all events, place limb and life in imminent jeopardy.   Above all, proper caution must be used if the patient is obliged to be transported to some hospital, or to a distant home, that he may not be subjected to unnecessary pain, exposed to loss of blood, or carried in a position incompatible with his exhausted condition.   Vast injury is often done in this way, by ignorant persons having charge of the case, and occasionally even by practitioners whose good sense should be a sufficient guarantee against such conduct.   The transportation of a patient to a distance of perhaps hundreds of miles upon a railway car, after he has been desperately wounded, in the hope, it may be, of obtaining better aid, cannot be too severely reprehended, as involving not only the loss of precious time, but often also the infliction of additional injury upon a part and system already overwhelmed by shock and hemorrhage.

Excision in gunshot and other injuries involving the articulations is, as will be more fully explained elsewhere, applicable chiefly to the shoulder and elbow joints, in cases unattended with serious lesion of the soft parts.   In the former, a portion of the humerus, embracing, if necessary, from three to five inches in length, together with a part or even the whole of the glenoid cavity of the scapula, may be safely and expeditiously removed under such circumstances, and yet the patient have an excellent use of his arm.   Experience shows that primary excision of the other joints, excepting, of course, the smaller ones, as those of the hand and foot, is generally very unfavorable.

Further observations upon this subject will appear in the chapters on amputation, fractures, dislocations, and excisions.

SECONDARY EFFECTS OF WOUNDS AND CONTUSIONS.

Every practitioner occasionally meets with cases of wounds and bruises in which the patient, happily escaping from the primary effects of the injury, suffers severely from what may be termed the secondary effects, coming on several weeks or months afterwards. These lesions have not received sufficient attention from systematic writers.   It has fallen to my lot to see a very large number of such cases, of which the following are selected in illustration of the subject:—

A farmer, thirty years of age, twisted and bruised his left foot in a fall from his horse. The accident was instantly followed by severe pain, and next day by excessive swelling, which, however, gradually subsided under the usual antiphlogistic remedies.   In the course of a few weeks the man was able to exercise on crutches, but the foot was now observed to be very sore and tender, cold, clammy, withered, benumbed, and completely destitute of power.   There was also frequent twitching of the three small toes, particularly at night, so as to interfere with sleep.   These symptoms were aggravated in damp, cold states of the atmosphere, when there were also occasionally neuralgic pains in the part.   The general health likewise materially suffered, the appetite being bad, the bowels irregular, and the mind much dejected.   When I saw the patient, nearly a year after the accident, he had been subjected to various plans of treatment, with hardly even any

temporary relief. Notwithstanding that he was placed upon tonics, alterants, and the hot and cold douches, with frictions with veratria liniment and the use of the bandage, many months elapsed before he experienced much benefit, and he has never entirely recovered the functions of his foot and ankle.

A man, twenty-five years of age, cut himself with an axe on the instep of the left foot, directly over the internal cuneiform bone. The weapon penetrated the bone, and evidently severed the extensor tendon of the great toe, as the toe could no longer be moved by the effort of the will. The wound healed completely in a few days, but shortly afterwards the parts became tender and remained so for several months. Meanwhile, the foot and leg grew sensibly thinner, and were habitually cold and clammy; a condition which has continued for several years. Whenever exercise is taken, the parts swell, and become tender. The muscles of the whole limb are flabby and wasted. The general health is much disordered; the man has lost thirty pounds of flesh, and he has been unable to attend to any business since the accident. His tongue is habitually coated, he sleeps badly at night, and he is subject to frequent fits of despondency.

A man, thirty-five years of age, consulted me on account of an accident similar to the above. He was a bricklayer by occupation, and had always been in good health until eight months previously, when he cut himself with a hatchet in the left instep, immediately over the internal cuneiform bone, as nearly as possible in the same situation as in the preceding case. The wound healed rapidly, but the patient soon began to experience exquisite pain and tenderness in the parts, extending up the leg, and subject to severe exacerbations from damp states of the atmosphere, exposure to cold, and derangement of the digestive organs. The suffering, which was irregular in its recurrence, was generally worse at night. The limb was cold and clammy, as well as much emaciated, and the parts immediately around the scar were hard, as if from the presence of organized lymph. The general health was much impaired, the tongue was coated, and the sleep was usually much interrupted, by spasm of the limb. A prominent symptom in the case was great soreness in the hollow of the foot, in front of the heel. When the man attempted to walk, the foot became very tender, and immediately began to swell. In this, as in the preceding case, the patient was obliged to use crutches.

A young lady, who had long suffered from dyspepsia and great nervousness, punctured the forepart of her right wrist, towards the ulnar margin of the forearm, with a small, slender sewing-needle, which entered the skin directly over the ulnar artery; and passed, apparently, obliquely inwards and outwards towards the centre of the joint, without, however, penetrating it. The needle was immediately withdrawn, but not examined, and the patient, consequently, was uncertain whether a portion had not broken off and remained behind. The accident was followed by most excruciating pain, pervading the entire extremity from one end to the other, but particularly severe at the seat of the injury and in the thumb and first two fingers. A violent rigor soon succeeded, and for ten days the patient suffered the most horrible torture, being frequently threatened with tetanus, and constantly annoyed with spasmodic twitches of the muscles of the hand and arm. Considerable swelling arose shortly after the receipt of the injury in the forearm, wrist, hand, thumb, and the fingers above named. At the end of the tenth day a small, circumscribed abscess formed at the site of the puncture, which, upon being opened, discharged about a drachm and a half of thick pus, much to the relief of the patient. In a week the matter had reaccumulated, and the part was again lanced, followed by the same relief as before. Subsequently the skin was scarified several times, the cuts bleeding profusely, but not yielding any pus. During the following summer she experienced severe and constant pain, especially in the anterior part of the arm, between the elbow and the insertion of the deltoid muscle; it was always more violent in the evening, and was of a dead, heavy, aching character. The limb was stiff and numb. Her hand and thumb, together with the fore and middle fingers, swelled every evening, becoming stiff and sore, so that she could with difficulty flex or extend them. During the day the parts always felt much more comfortable. Pressure at the seat of the puncture caused a sense of uneasiness rather than of pain, but was always followed soon after by so much distress as to prevent sleep during the succeeding night. The ring and little fingers were free from swelling, and easily moved. The whole limb was cold and considerably wasted. The probability is that, in this case, the needle pricked the ulnar nerve at the wrist, producing a condition, in her bad state of health, similar to that which occasionally results from the puncture of a nerve in bleeding at the arm. Under the use of an alterative and tonic course of treatment, with strychnia and arsenious acid, the hot and cold douches, frictions with veratria ointment, a nutritious diet, and exercise in the open air, the general

health rapidly improved, and the local suffering finally disappeared, although the limb never recovered its original powers.

Bad effects not unfrequently follow upon gunshot wounds; they present themselves in different forms and degrees, and often entail great suffering along with partial loss of function. Among the more common and annoying of these secondary effects are, as before stated, neuralgic pains and a sense of numbness in the parts, progressive atrophy of the muscles, contraction of the aponeuroses and tendons, and ankylosis of the joints.

In regard to the treatment of these secondary lesions, it is impossible to lay down any definite plan; every case must be managed according to the peculiarities of its symptoms. Much benefit may generally be expected from attention to the state of the general health, which is nearly always more or less seriously disordered. Neuralgic pains, altered sensibility, and atrophy usually require a course of tonics and arsenic, purgatives, the hot and cold douches, massage, or dry frictions, the use of the fringed towel, electricity, and other means to excite the vasomotor nerves. Rigidity of the joints must be counteracted by passive motion and sorbefacients; contraction of the tendons and aponeuroses by the use of splints and the bandage, aided, if necessary, by the knife. Change of air and sea bathing are often of signal benefit.

SECT. X.—POISONED WOUNDS.

Under this head are included four distinct classes of wounds: first, those inflicted by venomous insects and snakes; secondly, those caused by the bite of rabid animals; thirdly, those produced by inoculation with the poison of glanders; and, lastly, wounds received in the examination of dead bodies, constituting what are called dissection wounds.

1. WOUNDS INFLICTED BY POISONOUS INSECTS.

There are various genera of insects which naturally secrete a poison, which, when instilled into the living tissues, is capable of producing serious and even fatal consequences. Of these the most common, at least in this country, are the humble-bee, honey-bee, wasp, hornet, and yellow-jacket. The poison of these insects is contained in a small vesicle in the abdomen, and is under the control of a peculiar muscular apparatus by which it is injected into the puncture made by the barbed sting of these little creatures. It is highly acrid, especially in the honey-bee, hornet, and yellow-jacket, transparent, of a sweetish taste at first, but afterwards hot and disagreeable, and particularly active during the heat of summer. When angry, these insects sting with great fury, producing a wound which is instantly followed by a sharp, pungent, itching pain, and in a few moments after by a pale, circumscribed, inflammatory swelling. In some persons, owing to idiosyncrasy and other causes, the symptoms are exceedingly severe and even alarming, the patient having dimness of sight, vertigo, nausea, palpitation, and a feeling of indescribable oppression, with a disposition to syncope. Instances have occurred of persons having been stung to death by a single honey-bee; one such case, of which I have the particulars, occurred, many years ago, in Kentucky, in a man upwards of thirty years of age. He was wounded in the face, and died in a few hours. A young man, an acquaintance of mine, always suffers from severe sickness of the stomach and great nervous depression when stung by a bee. Violent effects sometimes proceed from the sting of a bee, wasp, or yellow-jacket in the fauces, œsophagus, or stomach, as when these insects are accidentally swallowed in cider and other drinks.

As the sting is often left in the skin, in the infliction of this class of wounds, the part should be carefully examined, in order that, if present, it may at once be extracted. The most promptly efficacious applications are generally salt water, alcohol, laudanum, vinegar, hartshorn, spirit of camphor, Cologne water, soap liniment, solutions of acetate of lead, dilute tincture of iodine, and tobacco-juice. Turpentine is also a very valuable remedy. Whether these and similar articles act by neutralizing the poison, or merely by relieving inflammation, is not ascertained. When the system becomes affected, internal stimulants, of which the best are brandy and ammonia, should immediately be used. If the insect has passed into the throat, a mustard and salt emetic will be the proper remedy, followed, if urgent swelling and impending suffocation ensue, by leeches to the neck, and, perhaps, by laryngotomy.

Various species of the *mosquito* tribes are poisonous, and, therefore, capable of inoculating the wounds made by their bite. In the Southern States, as well, indeed, as in some of the Western, and along many parts of the Atlantic coast, the mosquito exists in

vast numbers, and often inflicts serious injury, both upon man and animals. I have met with a number of instances in which the bite of this insect was productive of severe inflammation, and several in which it was followed by considerable ulceration. The late Professor Dorsey, of this city, observed a case of gangrene and death from a wound of this kind in a lady, previously in good health. So serious an effect as this is probably always dependent upon some idiosyncrasy, or upon the occurrence of erysipelas, consequent upon the bite. The stinging sensation and swelling which attend the application of the poison of the mosquito usually soon subside of their own accord, or under the use of some mild stimulant, as Cologne water, alcohol, vinegar, or laudanum. When the effect is more serious, tincture of iodine and warm water-dressing may be necessary.

The poison of the *scorpion* has many of the properties of that of the bee and wasp, although it is much more active. It is of a whitish color and oleaginous consistence, and is contained in a small reservoir near the end of the tail, whence it is ejected through two little pores on each side of the sting. In North America and Europe the wound inflicted by the insect is comparatively harmless, the only effect generally being a slight, transient inflammation; but in Africa and Asia it is often followed by great suffering and even loss of life, death sometimes occurring in a few hours. In those countries the scorpion frequently attains an enormous size, having a huge body, and a length of six to ten inches. Several species of this insect, of large size, are found in Cuba, Texas, Mexico, and South America, but I am not aware that their sting is particularly venomous. The great Eastern remedy in this variety of wound is olive oil, and an idea prevails that its virtues are greatly enhanced by infusing in it the bodies of some of these animals previous to its application. Spirit of hartshorn would doubtless be a more valuable addition. Such a wound should always be immediately well washed with salt water, then scarified, next thoroughly rubbed with volatile liniment, and then covered with an emollient poultice. If constitutional symptoms arise, they must be combated with anodynes, brandy, and ammonia, the treatment being very similar to that adopted for the sting of the bee and wasp.

Bad effects sometimes supervene upon the bite of the *spider;* and the fabulous stories about the poisonous qualities of the tarantula are known to every reader of history. The most prominent of these effects is a sense of itching at the wound soon followed by violent pain, difficulty of breathing, frequency and weakness of the pulse, nausea, copious perspiration, and general prostration. The symptoms of the bite of the tarantula are very similar to those produced by the sting of the common scorpion. The chief remedies in both cases are alcoholic and ammoniated stimulants, with opium, to relieve pain and to assist in sustaining the heart's action.

The bite of the *centiped*, which, in some countries, as the East and West Indies, Africa, South America, and the Southern regions of the United States, often attains a length of five to seven inches, is occasionally followed by severe symptoms, and even death, as in a case related by Dr. Lincecum, in the American Journal of the Medical Sciences for October, 1866. The poison bag, lodged near the base of the jaw of the insect, is of an oblong shape, and has a long, narrow, excretory canal, with a small opening at the extremity of the hooklet. The bite is exceedingly painful, and is frequently followed by considerable swelling and discoloration, along with more or less fever and even delirium. In the case observed by Dr. Lincecum, the patient survived the bite only about six hours. The prominent symptoms were, great general uneasiness, coming on immediately after the injury, excessive nausea, and frequent vomiting, which gradually increased in violence until the child, in a convulsive struggle, ceased to breathe. The whole surface was dappled with livid spots, from the size of a five-cent piece up to that of a dollar, and there was an elastic puffiness, giving the whole person a singularly tumid appearance. The treatment of such a wound must obviously be conducted upon the same general principles as the sting of the bee and other insects, the most reliable antidotes being ammonia and alcohol, along with anodynes. The immediate application of a cupping glass materially lessens the danger by preventing the ingress of the venom.

2. WOUNDS INFLICTED BY VENOMOUS SERPENTS.

The number of poisonous serpents in different parts of the world is very considerable; but in this country there are, so far as is at present known, only three genera that are at all dangerous on account of their bite. These are the crotalus, trigonocephalus, and elaps. Of the crotalus, or rattlesnake, so called from the peculiar appendage to its tail, Professor Holbrook, in his Herpetology of North America, has described not less than six species, of which the banded, striped, and miliary are the most common; all are

venomous, and, consequently, capable of inflicting deadly wounds. These reptiles formerly abounded in almost every section of the United States, especially in the swampy and mountainous regions, but are now very seldom met with in our denser settlements.

All the different species of rattlesnakes are provided with two small sacs, each of which contains a minute quantity of poison, and communicates, by means of a short excretory duct, with the canal in the fang on each side of the upper jaw. It is inclosed in a bony framework, situated external to the proper jaw, and is under the control of appropriate muscles, the action of which aids materially in expelling its contents. The fangs, situated just at the verge of the mouth, are very long, sharp, and crooked, like the claws of a cat, and are naturally retracted and concealed in a fold of integument; but, when the animal is irritated, are capable of being instantly raised, and darted forward with great force into the skin, followed by an emission of poison. The snake, then, does not bite, but strikes, making a punctured wound.

The annexed illustrations represent the head of the rattlesnake, and one of the poison fangs, with the canal along which the venom flows when the animal is in the act of inflicting its wound.
Fig. 117.   Fig. 118.

Fig. 117. Head of the Rattlesnake. *a, a.* Poison Gland, and its Excretory Duct; the latter cut open at its extremity. *e.* Anterior Temporal Muscle. *f.* Posterior Temporal Muscle. *g.* Digastric. *h.* External Pterygoid. *i.* Middle Temporal. *q.* Articulo-Maxillary Ligament, which joins the Aponeurotic Capsule of the Poison Gland. *r.* The Cervical Angular Muscle. *t.* Vertebro-Mandibular Muscle. *u.* Costo-Mandibular Muscle.

Fig. 118. Poison Fang, magnified. *p, p.* The Pulp Cavity of the Tooth. *v, v.* The Canal along which the Venom flows, truly on the outside of the Tooth.

The poison of the rattlesnake is a thin, semitransparent, albuminous fluid, of a yellowish color, with, occasionally, a tinge of green. According to Dr. S. Weir Mitchell, of this city, who has carefully studied its qualities, it is of a glutinous consistence, devoid of smell and taste, distinctly acid, of the specific gravity of 1044, and coagulable at a temperature of 143° to 160°. Its toxic activity is not materially, if at all, impaired by boiling and freezing, and alcohol, acids, alkalies, iodine, and chlorides do not destroy its virulence. When dried, it retains its noxious properties for an indefinite period. In an experiment performed by Dr. A. G. Taylor, two grains of the powder, which had been kept for twelve years, mixed with water, and injected under the skin of a rabbit, caused death in forty-five minutes. It contains, besides coloring matter, and an undetermined substance, both soluble in alcohol, a trace of fatty matter, chlorides and phosphates, and two albuminoid principles, one coagulable at 212°, the other, termed crotoline, not coagulable at this temperature, neutral in its action, freely soluble in water, and of a nitrogenous nature.

The quantity of venom contained in the poison-bag does not generally exceed a few drops; but it accumulates when the animal is inactive, and Dr. Mitchell had a snake which, on one occasion, ejected fifteen drops, its fang not having been used for several weeks. It is peculiarly acrid and deadly in hot weather and during the procreating season. In winter and early spring the reptile is in a torpid condition, and the poison is then diminished in quantity, and unusually thick, although not less virulent.

The effects of the wound of the rattlesnake vary with many circumstances, as the situation of the part, the acrid character of the poison, and the age of the patient. Experience has shown, as in the case of the bite of rabid animals, that most of those hurt in this way

escape either entirely or suffer only in a very slight degree; the poison either failing to reach the tissues, or being too inert to make any decided impression upon the system. It is also known that adults are less liable to suffer than children, simply because they possess, as may be supposed, greater vigor of constitution, and, consequently, greater power of withstanding the influence of the venom. The deleterious effects of the poison seem to be much weakened, if not actually exhausted, by a rapid succession of bites. The experiments of Captain Hall, of Carolina, and of Professor B. S. Barton, of this city, place this matter in a very clear light. Of three dogs bitten in succession by a rattle-snake four feet long, the former gentleman found that the first died in less than a quarter of a minute, the second in two hours, and the third in three hours. The subjects of Barton's experiments were chickens, and the results were almost identical with those of Hall. Of three fowls, bitten on three consecutive days, the first perished in a few hours, the second lived for some time, and the third finally recovered, although not without considerable suffering. Instances are occasionally met with in the human subject of almost instant destruction from the bite of the rattlesnake, as in a remarkable case which occurred at Baltimore, in which a man, bitten at two places on the cheek, died in twenty-eight minutes. In a case related by Dr. Shapleigh, of this city, death occurred in three-quarters of an hour, the man being struck on the forefinger, directly over the second joint. At other times the case proceeds more slowly, the patient surviving several hours, or, perhaps, even several weeks. Dr. Wainwright, of New York, lost his life in less than six hours from the time he was wounded. The reptile, an uncommonly large one, had lain in a torpid state for some time, when, unexpectedly becoming warmed, he struck his victim furiously on the last phalanx of the middle finger of the left hand. Although the wound was immediately sucked, and soon afterwards excised and cauterized, a ligature being also tied firmly round the wrist, the hand soon became enormously swollen, the tumefaction speedily extending up the limb nearly as far as the axilla, and the surface, in the greater part of its extent, exhibiting a mottled bluish and greenish-yellow hue. The pulse was very small and frequent, unconsciousness rapidly supervened, and the patient expired in a completely comatose state, preceded by nausea and excessive restlessness. Finally, in another series of cases, the patient, after having been near death's door for several weeks, eventually perishes or recovers. When death occurs almost instantaneously, the probability is that the poison is injected directly into the blood, the fang having penetrated some tolerably large vessel. Under such circumstances, the fluid is found to be thin, black, and uncoagulable on exposure to the atmosphere.

When this poison is freely instilled into a wound, the symptoms will always be proportionately severe. The moment the inoculation has taken place, excessive pain is experienced in the part, rapidly followed by swelling, which soon diffuses itself extensively over the surrounding surface, and is attended with a livid, mottled appearance, dependent upon extravasation of blood into the subcutaneous connective tissue. If the wound, for instance, occupies a finger, the tumefaction speedily extends up the limb, as far as the shoulder, and, perhaps, over a large portion of the corresponding side of the trunk, a feeling of numbness, weight, and coldness attending the other symptoms.

Within a few minutes after the first manifestation of the local affection, marked evidence appears of the absorption of the poison into the system. The patient looks excessively pale, sees objects indistinctly, is sick at the stomach, perhaps ejecting its contents, and has frequent swooning fits, with clammy sweats, and coldness of the body. By and by, as the system becomes more fully impressed with the deleterious effects, insatiable thirst arises; a sense of constriction is experienced in the chest; the breathing is oppressed; the pulse is feeble and vacillating; great anxiety and restlessness exist; the tendons twitch; the mind wanders, or is furiously delirious; and death soon closes the scene. In the worst cases of the affection, a universal yellowness of the skin is observed, and the parts are not only frightfully swollen, but, if the patient survive some hours, large vesicles appear upon the surface, containing bloody serum, and indicating the approach of mortification. When death does not take place for a considerable number of days, large abscesses form in the connective tissue under the skin and among the muscles, and the system gradually sinks under the resulting irritation.

The appearances presented in the bodies of those who die from the effects of this poison are pretty uniform. In the birds, rabbits, guinea-pigs, and dogs experimented upon by Dr. Mitchell, extravasation of blood and softening of the tissues in the neighborhood of the bite were almost invariably observed; the brain and spinal cord were more or less injected; the heart was distended and flabby; the lungs were sometimes engorged; and the intestines were occasionally ecchymosed. In several instances the kidneys were

acutely congested and filled with blood. The ureters and bladder contained sanguineous urine. The blood in the heart and vessels was dissolved, and of a dark color.

The genus *trigonocephalus* includes several species, of which the water moccasin, or cotton-mouth, and the copperhead, are the most important. They have no rattles, but the upper jaw is armed with poisonous fangs, and their bite is very deadly. The cotton-mouth snake is met with extensively in the Southern States, its northern limit being the Pedee River in North Carolina. Professor Holbrook states that it is the terror of the negroes about the rice plantations, being more dreaded by them than the rattlesnake, which attacks only when irritated, whereas the water moccasin makes war on everything that comes within its reach.

Of the genus *elaps*, the only species known in this country is the elaps fulvius, whose body, twenty inches in length, is of a beautiful red color, surrounded with black rings, margined with yellow. Its upper jaw is armed on each side with a permanently erect poisonous fang. It is found chiefly in the Southern States, in sweet potato fields, and is so gentle in its habits as to be regarded as almost harmless.

The most noxious serpent in the East Indies is the *cobra di capello*, the spectacled or hooded snake, of which there are a number of varieties, all distinguished for their venomous properties. The effects of its bite are very similar to those of the rattlesnake, only that they are generally somewhat more tardy, and accompanied by less swelling. The poison is of a semitransparent, yellowish appearance, not unlike olive oil. It has been known to kill a large dog in less than twenty minutes; and in the case of the keeper at the Zoological Gardens in London, who was bitten by a cobra on the root of the nose, death occurred in ninety-five minutes. The internal viscera were found, on dissection, to be intensely congested, and the blood, which was dark, alkaline, and fluid, emitted a peculiarly acid and sickening smell. In an instance observed by Sir George Ballingall, a girl, a native of India, expired in a quarter of an hour after she had been bitten by a serpent of this kind, notwithstanding the excision of the injured part, and the exhibition of large quantities of ammonia. Experiments performed by Sir Joseph Fayer, formerly of Calcutta, show that the poison of the cobra may exert its virulent effects by absorption through contact with the mucous and serous membranes. The poison of the phursa—the echis carinati of naturalists and the most common of all the East India serpents—is comparatively slow in its action, and only about 20 per cent. of the cases prove fatal.

In Europe, the *viper* is the most venomous serpent known. It is rare in England, but sufficiently common in France, Spain, and Italy, as well as in several of the more northern States of the Old World. The poison, which has a yellowish, oily appearance, may be swallowed almost with impunity, provided there is no abrasion upon the mouth. It is most active in hot weather, killing small birds and animals almost instantly. Applied to the human subject, it causes acute pain and diffused swelling, followed by a puffy, œdematous state of the subcutaneous connective tissue, and a livid and vesicated condition of the skin. The general symptoms, which seldom manifest themselves under three-quarters of an hour to an hour, bear so close a resemblance to those produced by the wound of the rattlesnake as to render it unnecessary to describe them.

A great deal has been written concerning the *treatment* of wounds inflicted by venomous serpents, and yet there is not a solitary reliable remedy. The fact that so many articles have been recommended as specifics clearly shows that these lesions are often so slight as not to require any treatment at all, the unpleasant effects generally passing off spontaneously in a few hours, either because the poison has not been introduced in sufficient quantity, or because it has been too inoxious to produce any serious harm. The first thing to be done, so far as the part is concerned, is to constrict the limb as tightly as possible, a short distance above the wound, which is then to be instantly excised and cupped, the glass being retained as long as the blood is disposed to flow, when the surface should be well washed with dilute tincture of iodine, the same remedy being thoroughly applied to the skin over the whole extent of the swelling. Subsequently, warm water-dressing, medicated with laudanum and acetate of lead, will form the most suitable application. Thorough constriction of the limb with Esmarch's bandage, or, in the absence of this, with a tightly drawn roller, might be of service in retarding the entrance of the poison into the system, and affording time for the operation of medicines administered internally.

The practice of sucking the wound is of great antiquity, and there have been men, from time to time, in different parts of the world, who have made it their special occupation. The Psylli, of Africa, and the Marsi, of Italy, acquired great celebrity for their skill in this business, and the custom still prevails among many of the Indian tribes of this

continent. The operation, however, cannot be performed with safety if there is any abrasion upon the lips or in the mouth, and should, therefore, always give way to the cupping glass.

Pain must be relieved, and the strength supported by morphia and alcohol, the latter being given, in any of its more common forms, to the utmost possible extent compatible with the patient's power of endurance. Whiskey is the great remedy, although it is not a specific, among the mountaineers of this country for this class of wounds, and there can be no question that it is entitled to great consideration. The treatment should be rapidly pushed to gentle inebriation, as men bitten when dead drunk have been known to die, although such an occurrence is seldom to be looked for when there is such marked depression of the general system as so often attends this lesion. Ammonia may occasionally be advantageously combined with the alcohol on account of its diffusible stimulating properties. When there is excessive prostration, along with great gastric irritability, enemata of brandy and laudanum should be employed. Olive oil has been highly recommended as an antidote against snake-bite; but experience has shown that it possesses no such virtues. In the East Indies, the Tanjore pill formerly enjoyed great celebrity in the treatment of wounds inoculated with the poison of the cobra di capello and other noxious serpents, its efficacy being supposed to depend upon the arsenic which enters into its composition. Fowler's solution has also been much lauded for its supposed neutralizing qualities, especially of the poison of the fer-de-lance, a venomous serpent in the Island of St. Lucia: it is administered every three hours in doses of two drachms along with a small quantity of laudanum, until active vomiting and purging are induced. But none of these remedies are reliable, and my opinion is that no time should be wasted upon their exhibition.

In the first edition of this work attention was directed to the use of Bibron's antidote, as it has been called—a mixture of bromine, iodide of potassium, and bichloride of mercury—as a means of neutralizing the effects of the poison of the rattlesnake; but it has been ascertained by Dr. Mitchell that it possesses no such properties; nor are arsenic and ammonia, or, indeed, any other articles of the materia medica, so far as we know, endowed with such virtues. In regard to topical remedies, he found, experimentally, that iodine, injected subcutaneously, as originally suggested by Brainard, of Chicago, exerted a great influence over the local effects of the venom, but none in preserving life or defending the system at large. Some simple astringents also possess this power, and are equally as useful as iodine. Carbolic acid, injected into the envenomed tissues, sometimes delays the fatal result, and usually lessens the local hemorrhage. Among the internal stimulants, he assigns, in common with all American practitioners, the highest rank to alcohol, looking upon it, not as a chemical antidote, or neutralizer of the venom, but as a great supporter of the vital forces. When the patient is too weak or too sick to swallow, it may be administered in the form of an enema; and in that event, the inhalation of hot alcohol, or even of ether, will be of service as a means of reëxciting the flagging energies of the system. In a severe case of rattlesnake poisoning, recently under the care of Dr. Moorman and Dr. Fuqua, large quantities of iodide of potassium conjoined with alcoholic stimulation seem to have been attended with marked benefit, the patient making a good recovery, although the limb was enormously swollen, and the system greatly exhausted. When the immediate effects of the poison have passed off, quinine and a nutritious diet will be necessary, along with spirituous stimulants, to aid restoration. Dr. Mitchell has ascertained, by direct experiment, that carbolic acid and the sulphites of sodium and lime possess no antidotal power.

Finally, it may be observed, in regard to the so-called antidotes for snake-bite, that the remedies which have, from time to time, been invested with this virtue, doubtless owed their temporary reputation to the fact that the cases in which they were used were cases of a comparatively slight character, which would probably have recovered as well, or nearly as well, without as with their use. The history of surgery certainly warrants this conclusion.

3. WOUNDS INFLICTED BY RABID ANIMALS.

There is a peculiar disease in man and animals known by the name of hydrophobia, its characteristic symptoms, at least in the human subject, being a dread of water, as the term by which it is generally designated literally signifies. It is due to the influence of a particular poison, generated by certain animals, and capable of propagating the disease by inoculation. Of the nature of this poison all that is known is that it is contained in the saliva, and that, after having remained latent for some time in the wounded part, it

is absorbed and carried into the system, where it produces the peculiar effects by which the malady is distinguished.

That the virus of hydrophobia resides in the saliva, and not in the secretion of the mucous follicles of the mouth and fauces, has been fully established by experiments upon the inferior animals. Thus, Zinc inoculated a dog, cat, hare, and cock, with the saliva of a rabid dog, and readily induced the disease. Similar results followed the investigations of Depuy, Youatt, and other veterinary surgeons. The former of these writers rubbed a sponge wet with the saliva of a mad dog upon the sore of a sheep, which subsequently perished from hydrophobia; and the latter communicated the affection from one brute to another by means simply of a silk thread, impregnated with this fluid and used as a seton. If further proof of this fact were needed, it could be found in the experiments of Raymond, who repeatedly induced the disease in healthy rabbits by inoculating them with the salivary glands of rabid ones. Magendie and Breschet developed hydrophobia in dogs by inserting frothy fluid taken from the mouths of human beings affected with rabies. Dr. Gaultier, of Lyons, finds that the saliva of a rabid dog is perfectly harmless if injected into a vein, and that its contact with the nerves is indispensably necessary to produce the disease.

It is supposed by many pathologists, as Bouley, Fleming, Lindsay, and Brueckenmueller, that certain animals, as the dog, wolf, fox, jackall, and badger, if not also the cat, tiger, and lion, have the faculty of generating the virus of hydrophobia spontaneously; while others, as Magendie, Dupuytren, Breschet, Bollinger, and Virchow, positively assert that rabies can only originate from inoculation with the peculiar virus of this disease. The latter doctrine is certainly the more plausible of the two, as it is much more in accordance with our knowledge of the habits of other poisons. I cannot, indeed, see how the affection could be induced in any other manner. It is extremely probable that all the higher classes of animals are capable of contracting hydrophobia by inoculation. Breschet repeatedly induced it in dogs by inserting the saliva of rabid horses and asses; and cases have been reported of human beings having suffered from the bite of rabid horses and pigs. It is uncertain whether hydrophobia can be communicated from one person to another. In the case of Wheeler, a dresser at Guy's Hospital, London, who was bitten by a rabid patient, no ill effects followed, and I know of no well-authenticated instance of the disease having been produced in this wise. Rabbits and similar animals, as well as fowls, soon die from inoculation with this poison, without exhibiting any of the ordinary symptoms of hydrophobia.

The inoculation in hydrophobia is usually effected by the teeth, which, however, need not necessarily penetrate the true skin, as the disease may readily be communicated by the slightest scratch or abrasion. An instance has been reported in which death was produced by the licking of a wart upon the face, by a poodle supposed to be laboring under rabies. It has been conjectured that the disease may be communicated merely by the contact of the saliva of a hydrophobic animal with sound skin and mucous membrane. It is also believed to be possible that a mother may transmit the affection to her infant through her own milk. Cases now and then occur which lead to the suspicion that the disease may be induced by dogs and other animals not actually mad, but simply enraged, or in which the disease is simply in its incubative state. Finally, experiments have been performed which prove that the morbid saliva may be administered internally with entire impunity.

It is notorious that many of the persons bitten by rabid animals do not contract hydrophobia, the saliva containing the specific virus being no doubt wiped off as the teeth penetrate the clothes. Hunter and Hamilton supposed that out of twenty or thirty persons bitten only one would take the disease, an estimate altogether too low. The wounds inflicted by rabid wolves are much more dangerous than those of rabid dogs, the differences being due to the fact either that the virus of the former animals is more virulent than that of the latter, or else that wolves generally attack the exposed parts of the body, as the face, neck, and hands, whereas dogs more generally infix their teeth into those that are covered. Of 254 persons bitten by rabid wolves, 164, according to Renault, died of hydrophobia. For a similar reason the bite of a cat is always peculiarly dangerous.

The period of latency of this disease varies from a few weeks to several months. In 89 cases, analyzed by Dr. Blatchford and Dr. Spoor, of Troy, the average period was about seventy days, the minimum in 23 cases was thirty days and under, and the maximum in 6 cases was upwards of two hundred days. According to Bollinger sixty per cent. of all cases occur between eighteen and sixty-four days. In the only three cases of hydrophobia that I have ever seen, the disease appeared, in two, at the end of four weeks, and in

the other nine months from the date of the inoculation. In an instance under the care of Dr. Demme, of this city, the patient, a man, aged twenty-six, had been bitten eighteen months previously. Dr. J. W. Lodge has reported to me the particulars of a case of hydrophobia in a child three years old, in which the period of latency was precisely seven weeks. According to John Hunter, the extremes range from thirty days to eighteen months. Wenderburg has related an example in which the poison remained quiescent for four years; Breva, one of five years; and Bardsley, one of twelve years; each, apparently, well authenticated, and yet wholly unreliable. An undoubted case of hydrophobia, in which the poison remained in a latent condition for nearly three years and a half, occurred in this city last winter, in a young man, twenty-two years of age. Death took place in less than three days from the commencement of the attack. The time of incubation is generally considerably shorter in animals than in man, and in very young persons than in adults.

Although a considerable period always elapses between the inoculation and the appearance of hydrophobic symptoms, it is extremely probable that the virus is speedily absorbed into the system, although some time is necessary to develop its zymotic properties. What countenances this view is that nearly all the other known poisons, when brought in contact with the living tissues, are promptly absorbed, so as to make, sooner or later, their peculiar impression upon the constitution. The poison of syphilis is absorbed very speedily, and the probability is that the same is true with respect to the virus of smallpox, measles, scarlatina, and other zymotic affection. A certain period, however, is necessary, in every case, to enable the poison to explode upon the general system, or, in other words, to increase its virulence and extend its influence. With regard to the virus of rabies, it is a well-known fact that the disease is often developed within the usual period, after the most prompt and thorough excision of the bitten parts.

When the virus lies in a dormant state for an unusually long period, it is no doubt locked up, as it were, in the cicatrical tissues of the wound in such a manner as to be unable to extricate itself until, by some organic changes, of the precise nature of which we are ignorant, they are so softened and disintegrated as to bring it under the control of the absorbent vessels, through the agency of which it finally gains admission into the system.

Many persons are bitten by rabid animals and yet never contract the disease, the virus having either been exhausted before the rencontre takes place, or, what is more probable, having been wiped off by the clothes in the act of inflicting the wound. In this way more than half of those bitten occasionally escape with impunity; on the other hand, it sometimes happens that nearly every one is effectually inoculated. It is not impossible that idiosyncrasy may exert an important influence in the production of the disease. It is well known that this is true of other zymotic poisons, and it is, therefore, reasonable to suppose that it may also hold good of this. Of fifty dogs inoculated by Dr. Herwitch, of Berlin, with saliva taken from a rabid animal of the same species, not one in five was affected.

Hydrophobia is not peculiar to any age. It has been observed in infants at the breast, in children, and at every period of adult life. It occurs in all countries, in all climates, and at all seasons of the year. France, Italy, Austria, Russia, and Germany, however, have furnished a greater number of cases than any other parts of the world. It is also frequently met with in England; and, as a general rule, it is more common in northern than in southern regions. Throughout the West Indies it is comparatively rare, although the number of dogs there is unusually great as compared with the number of inhabitants. Hydrophobia is more common in Canada and New England than in the Southern States of the Union. Of 2520 cases observed on the continent of Europe, in Great Britain, and in the United States, and referred to by Dr. Charles P. Russell, in Johnson's Universal Cyclopædia, 1704 occurred in the spring, 621 in the summer, 608 in the autumn, and 587 in the winter, thus showing that the influence of season is comparatively slight.

The *symptoms* of rabies necessarily divide themselves into local and constitutional; or those furnished by the wounded part, and those afforded by the system, after the absorption of the specific virus.

The wound inflicted by a rabid animal generally heals as kindly as any similar wound made by a sound animal; the scar, perhaps, remaining a little red and tender, as it usually does after an ordinary bite, but exhibiting no other peculiarity, and the system being perfectly free from disease. By and by, however, when the period of incubation is about to draw to a close, the part begins to itch, burn, or smart, and soon becomes sore and irritable, hot, numb, or rigid, pain darting through it in different directions, and sometimes extending to a considerable distance beyond the site of injury, as from the

hand up to the shoulder, or from the foot to the knee or groin. Sometimes the wound reopens, the cicatrice gives way, or red lines are traceable in the direction of the lymphatics. Almost simultaneously with the local affection, evidence of general indisposition appears. The patient feels unwell; his head aches; his sleep is disturbed by unpleasant dreams; he feels melancholy and depressed; and he has occasional attacks of chilliness, with a highly impressible state of the system. The poison is now fairly at work, and in a few hours—generally from twelve to twenty-four—explodes with frightful violence. The period of latency is passed; the disease has reached its second stage; the dread of water and the difficulty of deglutition have declared themselves; in a word, hydrophobia is fully established. The patient, on attempting to drink, is suddenly seized with spasm in the throat, and finds that he is unable to swallow a particle of fluid; he tries and tries, but every effort is only succeeded by a renewal of suffering, and presently he dashes away the cup as if it were charged with some deadly poison, unwilling again to bring it to his lips. Tortured with thirst and a sense of dryness of the mouth, he will endure his discomfort rather than subject himself to the dreaded spasm. Should he succeed in forcing down a little water, he will be instantly seized with suffocative cough, convulsive tremors, and lividity of the face, compelling him to jump up in bed, and to pant for breath. The painful sensations are usually referred to the throat, and are often accompanied by a feeling of constriction in the chest, difficulty of respiration, a disposition to sigh, and a frequent desire to clear the mouth and fauces, which soon become clogged with an inordinate secretion of thick, viscid saliva and mucus, which greatly aggravate the patient's suffering. At this stage of the disease, and, generally, indeed, before it has reached this point, there is superadded to the previous distress a remarkable susceptibility to atmospheric impressions, the slightest contact of cold air being a source of profound torture, producing a sense of suffocation and even violent convulsions. The agony thus occasioned is sometimes much greater than that caused by the attempt to swallow fluids. The least opening of a door, the slightest motion of a fan, or even the smallest whiff of air directed from the attendant's mouth upon the body, instantly brings on a paroxysm of this kind. Light and noise, too, are always offensive; and hence the patient usually insists upon his room being kept dark, quiet, and closed. The mind, at this stage, is peevish and fretful, and nothing that can be done pleases the sufferer, who, in consequence, often quarrels with his best friends. At times his imagination is completely perverted; he fancies that he hears noises and sees objects that have no real existence; he gets out of bed, walks about the room, screams, or gesticulates, very much like one affected with delirium tremens.

In the last stage, which is characterized by an aggravation of all the previous symptoms, the countenance has a haggard and distressed appearance, horror and anxiety being depicted on every feature. The pupils are dilated, and the eyes have a wild, glaring expression; the tongue is dry and parched; the voice is hoarse and shrill, almost like that of a dog; the respiration is short and panting; more or less delirium is present, often amounting to complete mania; the strength is much impaired; and the pulse, small and feeble, beats from one hundred and thirty to one hundred and sixty in the minute. Thus the disease progresses, paroxysm after paroxysm recurring until the frame is worn out by exhaustion, death usually taking place suddenly in a fit of suffocation. Occasionally a slight calm is experienced a few hours before the fatal event; the spasms almost completely subside, the power of swallowing returns, the mind becomes clear, and the patient, perhaps, sinks into a tranquil sleep. The duration of the attack varies, on an average, from thirty-six hours to three days.

In a case of hydrophobia which I attended in 1842, the patient, a young man, twenty-one years of age, was attacked precisely four weeks after having been bitten in the left hand by a rabid dog. When I first saw him the disease was already in its second stage, well-marked symptoms having appeared the previous day. The difficulty of swallowing and the morbid sensibility of the skin were present in a high degree. Every effort at drinking, nay, the very mention of fluid of any kind, and the attempt to raise the glass to the lips, caused violent convulsions; the countenance was flushed and tumid; the eye red and suffused; the mouth parched; the throat clogged with viscid mucus; the pulse frequent and rather strong; the respiration hurried; the thirst and restlessness intense; the mind exceedingly peevish and irritable; and the sensibility of the skin so exalted that the slightest approach to a current of air, inappreciable by any one else, produced the most horrible torture. The inability to bear light and noise was also very great. The hand felt numb and painful, although the wound had not reopened. These symptoms gradually progressed, increasing steadily in severity, until towards the end of the third

day from the attack, when the young man expired in a state of complete exhaustion. The pulse, during the latter stage of the malady, was exceedingly irregular, and upwards of one hundred and fifty in the minute; the breathing was short and panting; and the mind was excessively agitated and distressed, but clear and intelligent, except when a convulsion was about to occur. The voice was not materially affected.

It is impossible to mistake hydrophobia for any other disease. The dread of water, the difficulty of deglutition, and the suffering occasioned by the contact of cold air, are always sufficiently diagnostic of the affection, even when no history of it can be obtained.

The *dissection* of persons dead of this disease has thrown no light upon its seat or its pathology. In the case of a young man of twenty-four, who died in 1840, nine months after he had been bitten on the hand, and whose body I assisted in examining, no lesion whatever could be detected by the closest scrutiny. The mouth, fauces, pharynx, and œsophagus, the larynx, trachea, and bronchial tubes, where disease might naturally be supposed to exist, under such circumstances, were perfectly free from morbid appearances. The brain and spinal cord, lungs, stomach, bowels, and other viscera, were equally sound. Occasionally, especially in protracted instances, the membranes of the brain have been found congested, and the ventricles partially filled with serum. The stomach, œsophagus, and pharynx have also been found inflamed; and several cases are mentioned where pus was discovered in some of the larger joints. Very little reliance, however, it seems to me, should be placed upon such reports, especially when we consider the loose manner in which most of them are drawn up, and the fact that comparatively few men are competent to make accurate dissections. Microscopic inspection in the hands of Meynert, Benedict, Hammond, Schultze, Wassilieff, Gower, and others, has thrown no reliable light upon the subject.

The *prognosis* of hydrophobia is always bad, the disease invariably ending fatally. There is no case of recovery, of a reliable character, upon record. I know that a number of instances have been published in which the patient is said to have got well, but there is not a single one, so far as my information extends, that can withstand the test of scientific scrutiny.

The period at which death occurs is generally very short. The average in 72 cases, analyzed by Blatchford and Spoor, was three days. Of 120 cases, collected by Dr. J. L. Smith, of New York, 65 perished in from one to two days. In some instances the disease proves fatal during the first twenty-four hours, while in others this event does not happen until the tenth day, although when postponed so late it must necessarily create very great doubt as to its true nature.

In the *treatment* of this variety of poisoned wounds, reliance must be placed solely upon preventive measures; for, as just stated, when the disease is once developed, there is no possible chance of doing anything more than mitigating the suffering, and even that only in a slight degree. If, as I have supposed, it be true that the poison is speedily absorbed after being brought into contact with the living tissues, the importance of promptly dislodging it cannot be too forcibly impressed upon the attention of the practitioner. As soon, therefore, as such a case is presented to his notice, the injured part should be thoroughly excised, along with a portion of the sound tissues. The flow of blood is then to be encouraged with a cupping glass, retained for some time, when the raw surface is well cleansed, and immediately cauterized with nitrate of silver. If the teeth of the rabid animal have penetrated between two bones, as, for example, when the bite has been inflicted upon the hand, excision must be performed with increased care, otherwise a portion of the virus will be liable to be left behind. In such a case it might become a nice question to determine whether the operation should not be made to include a portion of the bones also; for almost any local sacrifice is justifiable to secure immunity from so horrible a disease. It would seem from the observations of Mr. Youatt and Mr. Blane, two eminent veterinary surgeons, that there is no remedy which so certainly neutralizes this poison as nitrate of silver. The former of these writers, whose opinion is entitled to the greatest respect on account of his large experience in the treatment of canine madness, states that he employed this article in upwards of 400 persons, as well as repeatedly upon himself, with complete success, and such was his confidence in its virtues that he regarded it in the light of a specific. His plan was to cleanse the parts well with soap and water, and then to cauterize them most thoroughly, previously enlarging the wound, if necessary. If I were myself so unfortunate as to receive such an injury, I should certainly feel more confidence in my escape, if the wounded structures had been excised and cupped prior to the application of the caustic.

Excision should also be practised even when the injured part has been neglected, or imperfectly removed in the first instance, it being well known that the individual may escape the constitutional effects of the disease after the wound has begun to fester, or after it has partially reopened. But even if there were no hope of preventing the development of the disease by this procedure, it should, nevertheless, be adopted if for no other reason than the soothing effect it would exert upon the mind of the poor sufferer. Everything tending to allay his fears and contribute to his comfort is justifiable under such trying circumstances. If the symptoms of hydrophobia, however, have already been developed, neither such an operation, nor even the amputation of the limb above the site of injury, can be of any service.

When the poison has reached the system, and has evinced its explosive effects, no treatment, however judiciously and perseveringly conducted, is of any avail as a curative agent. The experience of two thousand five hundred years fully attests the truth of this statement. The whole materia medica has been exhausted in search of a remedy for this disease, and there is hardly any article, vegetable or mineral, that has not been used, either singly or combinedly, and yet no instance has ever occurred in which any permanent benefit ensued.

To relieve the frightful suffering from the disease, chloroform and ether, either alone, or variously combined; morphia, in large quantities in the form of hypodermic injections, frequently repeated; the application of steam conveyed to the patient's body as he lies in bed; and the exclusion of cold air, noise, and light from the apartment, constitute the most reliable means. General bleeding, the hot bath, and tartar emetic, so much vaunted by some, will only expedite the fatal issue, without affording any decided mitigation of the suffering. Opium is of no use, even if given in enormous quantity, as the stomach cannot dissolve it. An ice bag stretched along the spine may do good by allaying nervous excitability. The food should be given in the most concentrated form, or what is preferable, administered by the rectum. Dr. Physick, with a view of relieving the dyspnœa, and preventing suffocation, advised laryngotomy, but I am not aware that it has ever been practised, or, if practised, that it has ever done any good. It certainly could not cure the disease, and it admits of doubt whether it would even moderate the spasm. More benefit will, I am sure, accrue from the hypodermic use of morphia, and from the exhibition of the bromides and of chloral, in allaying the terrible distress, mental and corporeal, than from all other means combined, unless an exception be made in favor of nitrite of amyl, to which attention was called in connection with this affection, in 1877, by Dr. William S. Foster, of this city. Administered in doses of fifteen to twenty-five drops in the form of inhalation, it promptly calms the system, and enables the poor sufferer to swallow fluids with the greatest facility, a property which, so far as is now known, no other remedy possesses in such condition of the system.

Hydrophobia in the Dog.—In concluding the subject of hydrophobia, a few remarks may be made respecting the character of this disease as it occurs in the dog, as it is important for the practitioner to be able to judge of the probability of his having been mad in the event of his having bitten a human being.

How the disease originates in the dog is not ascertained. It has been supposed that unsatisfied salacity, the use of filthy and unwholesome food, too close confinement, and extremes of heat and cold, constitute so many causes of the malady; but it is obvious that, although this may be true, our knowledge at present amounts to nothing but conjecture, which further and more carefully conducted observation alone can either verify or disprove. The average period of incubation is about forty days, the minimum being a fortnight, and the maximum three months and a half. The higher classes of dogs suffer less frequently from hydrophobia than the mongrel breeds, and it is also affirmed that bitches are less liable to the disease than males; a statement which requires further proof before it can be accepted as true.

The early symptoms of rabies in the dog are thus graphically described by Mr. Youatt: "In the greater number of cases," he remarks, "there are sullenness, fidgetiness, and continual shifting of posture. When I have had opportunity, I have generally found these circumstances in succession. For several successive hours perhaps he retreats to his basket or his bed. He shows no disposition to bite, and he answers the call upon him laggardly. He is curled up, and his face is buried between his paws and his breast. At length he begins to be fidgety. He searches out new resting-places; but he very soon changes them for others. He takes again to his own bed; but he is continually shifting his posture. He begins to gaze strangely about him as he lies on his bed. His counte-

nance is clouded and suspicious. He comes to one and another of the family, and he fixes on them a steadfast gaze, as if he would read their very thoughts. ' I feel strangely ill,' he seems to say : ' have you anything to do with it? or you? or you?' Has not a dog mind enough for this? If we have observed a rabid dog at the commencement of the disease, we have seen this to the very life." Delirium is an early and characteristic symptom ; the dog sees imaginary objects, and often springs at them with a furious dart ; he is restless and excessively irritable, gazing wildly around, and snapping at everything within his reach. The saliva is secreted profusely, and collecting at the corners of the mouth, the animal makes frequent attempts to detach it with his paws ; his appetite is strangely perverted, and he will sometimes greedily devour horsedung, or even his own excrements ; the voice is changed in its character, being generally hoarse, and more or less shrill ; the eyes are singularly bright ; and the thirst is intense and insatiable, the dog drinking frequently, and having no fear whatever of water, as is the case with the human subject.

The disease is now in full force, and tending rapidly to a fatal issue. The muscular powers being greatly exhausted, the animal finds it difficult to sustain himself upon his limbs ; he reels and staggers about like a man in a drunken fit ; his tail is depressed, and the tongue protruded ; the eyes have lost their brightness, and are of a dull, glassy appearance ; the respiration is hurried and panting ; finally, worn out by his suffering, the poor creature dies, either from convulsions, or from sheer exhaustion, the duration of the attack varying from three to five days. The power of communicating the infection exists, according to Youatt, in all the confirmed stages of the disease, and continues even for twenty-four hours after the death of the animal.

4. GLANDERS, FARCY, OR EQUINIA.

The horse, ass, and mule are capable of spontaneously generating a disease, which, although it affects the whole system, expends itself with peculiar force and virulence upon the mucous membrane of the nose, causing violent inflammation and a copious discharge of thick, fetid matter. It is accompanied by a pustular eruption of the skin ; and the name by which it is generally known is glanders, from the fact that it is always associated with disease of the maxillary and of the lymphatic glands of the ear and neck. There is a form of the affection which is characterized by the development of small tumors beneath the skin in different parts of the body, varying from the size of a pea up to that of a hazel-nut, of a spherical shape, very hard, almost immovable, and generally exquisitely painful to the touch. When very numerous, they give the surface a remarkably tuberculated appearance. To this disease the term farcy is commonly applied ; and an attempt has been made by several writers to establish for it a distinctive character. Others, on the contrary, assert that it is identical with glanders, differing from it only in its location, or in the character of the structures in which it appears. This view of the case derives confirmation from the fact that the two affections often coexist, which could hardly happen if they did not possess a strong natural affinity for each other.

It is not likely that this disease, as was once supposed, arises spontaneously ; on the contrary, there is every reason to believe that it is invariably the result of the action of a peculiar virus generated during the existence of glanders. Absorption is generally effected with wonderful rapidity. Renault, surgeon to the Veterinary School at Alfort, inserted the poison into horses, and, although the wounded part was excised and thoroughly cauterized within one hour afterwards, they all died from the disease. Whatever its true nature may be, it is certain that the strongest and most healthy animals speedily contract it when exposed to its influence, hard usage, inadequate feeding, and confinement in damp and ill-ventilated stables, especially if underground, powerfully predisposing to its occurrence. It was at one time thought questionable whether the disease could be propagated by atmospheric agency ; but multiplied observation long ago fully settled that point. It would seem, indeed, that the air of an infected stable, after all the wood work, pavement, and plastering have been completely replaced, and every possible precaution used in regard to cleanliness, is capable of reproducing the disease in all its former severity.

The fact that glanders may occur in the human subject was first enunciated by Mr. Muscroft, in the Edinburgh Medical and Surgical Journal, in 1821. The case was that of a man who had accidentally inoculated his hand in cutting up a horse that had died of this disease ; violent symptoms soon showed themselves, and he expired in great agony at the end of a week. Since that time a number of similar examples have been recorded by other observers, thus indisputably establishing the transmissibility of glanders from

animals to the human subject. As yet no facts had occurred proving that the affection might be communicated from one human being to another, or from man to beast. In 1840, however, a case of this kind was admitted into St. Bartholomew's Hospital, London, which conclusively settled the question. The patient, a knacker, had died of glanders, and the nurse who attended him took the disease and also perished from it.

These facts regarding the transmissibility of glanders from animal to man, from man to man, and finally from man to beast, are of great pathological interest, and serve to inculcate the great necessity of caution on the part of the professional attendants and nurses in their intercourse with persons laboring under this horrible disease; since the smallest particle of the specific virus coming in contact with an abraded surface, or even the mere inhalation of the infected air of the patient's apartment, may give rise to the malady.

In the equine tribes of animals, glanders may be propagated by inoculation with the pus and mucus of the pituitary membrane, the fluids being inserted under the skin with a lancet, or rubbed upon the greasy heel of the horse. It may also be produced by applying these secretions to the mucous lining of the nose; and a curious case has been reported of its having been caused by introducing balls of farcied matter into the stomach. The poison of glanders seems to enter the system very rapidly; sometimes, indeed, almost instantaneously. Bouley and others of the Veterinary School at Alfort inoculated horses with the pus of this disease; and, although the inoculated structures were cut out one minute after its insertion, glanders speedily followed. An experiment performed by Mr. Coleman, of London, shows that the blood of an infected animal transfused into the carotid artery of a sound one, will rapidly engender the malady in its most virulent form.

The period of *latency* of this disease is generally very short, rarely exceeding two or three days. It is probably a little longer in the human subject than in animals, but the difference, if any, is very slight. It has already been seen that the first case that ever occurred, so far as is ascertained, in the human subject, terminated fatally at the end of a week from the time of the inoculation. The first local evidence of the disease is generally some swelling and tenderness of the maxillary glands, and inflammation of the mucous membrane of the nose; sometimes the one, at other times the other, taking precedence.

The *symptoms* of glanders naturally divide themselves into constitutional and local. Shortly after the inoculation, the patient begins to feel unwell; his head, back and limbs ache; chilly sensations, alternating with flushes of heat, creep over his body; sleep and appetite are impaired; the strength sensibly diminishes; the joints are stiff and sore; the spirits are depressed; the stomach is irritable; and the bowels are costive. After the lapse of twenty-four to forty-eight hours, a severe and protracted rigor generally occurs, followed by violent fever, profuse perspiration, and a marked elevation of temperature, the thermometer often rising to $102°, 103°$, or even $104°$ Fahr.; an evidence that the stage of incubation is passed, and that the poison has gained full admission into the system. The symptoms now rapidly assume a typhoid character. The pulse becomes quick, frequent, and tremulous; the tongue is dry and brownish; sordes accumulate upon the gums and teeth; the voice is weak and often husky; the respiration is short, panting, and accompanied by a sense of constriction across the chest; the surface is bathed with fetid, clammy perspiration; the thirst and jactitation are excessive; the urine is scanty and high-colored; the alvine evacuations are slimy and extremely offensive; the mind wanders; and the pains are atrocious.

Coincident with these phenomena there are marks of serious disease of the mucous membrane of the nose, which is highly inflamed, and the seat of a copious, viscid, and irritating discharge. Excessive pain and soreness exist in the forehead, over the frontal sinuses, evidently from an extension of the inflammation to the lining membrane of those cavities; and for the same reason there is generally great uneasiness in the throat and larynx. The nose and cheeks soon become hot, swollen, purple, excoriated, and exquisitely painful; the discharge from the nostrils assumes a bloody, purulent character, and is both copious and disgustingly offensive; the eyelids are infiltrated and nearly closed; and the features are hideously disfigured. About the tenth or twelfth day hard pustules make their appearance on various parts of the body, especially on the trunk, face, genital organs, and inside of the limbs, resembling those of smallpox, and attended with profuse, fetid sweats. Occasionally they are accompanied by black bullæ, which, breaking, discharge a thin, sanious fluid, and bring into view gangrenous spots, varying from the size of a three-cent piece to that of a quarter of a dollar. In some cases, again, numerous tubercles appear in different situations, interspersed among the pustules, or pustules and vesicles; they are generally small, of a roundish shape, hard, and exceedingly painful; as the disease proceeds, they give way on the surface, and exude a thin, ichorous fluid. The

lymphatic glands of the groin, axilla, and other regions frequently participate in the disease, becoming enlarged, tender, and painful; the lungs are also apt to suffer, and, indeed, it is not uncommon to see serious involvement of various viscera.

As the disease progresses, the prostration rapidly increases; the fever displays a more malignant character; deep coma supervenes; and the body exhales a horribly offensive odor, almost characteristic of the disease, and strongly denotive of the dissolved state of the blood and the putrescent nature of the secretions.

The period at which death occurs varies from eight or ten days to four or five weeks. In a majority of the reported cases, the disease terminated fatally before the eighteenth day; some of the patients died as early as the end of the first week, while a few lived until after the fiftieth day.

When glanders pursues this rapid course it is said to be acute, and chronic when it is more tardy. In the former case, the local symptoms usually precede the general, frequently setting in within a few hours after the absorption of the virus. The inoculated part becomes red and tender, and the epidermis is soon elevated into a vesicle, or pustule, from which the inflammation rapidly extends along the lymphatic vessels as high generally as the glands of the groin or axilla. The swelling is excessive; the limb is stiff and numb; and the connective tissue, infiltrated with sero-albuminous exudation, before long becomes the seat of numerous abscesses. In the more severe cases, black spots appear upon the surface, indicative of the existence of gangrene. Sometimes the local disease begins in the lymphatic glands of the groin or axilla, from which it spreads over the corresponding side of the trunk, and even over the whole limb.

In contemplating the progress of this disease, it is impossible not to be struck with the resemblance which it bears to that of a dissection wound. It evidently belongs to the hemotoxic class of affections, consisting essentially in a disorganized condition of the blood and solids, paralyzing and crippling the heart and brain, and thus bringing about that typhoid condition of the system which forms so prominent a feature of the complaint.

Dissection always discloses the existence of serious lesions in the nose and internal organs. The pituitary membrane, of a deep purple or livid hue, is coated with tough, viscid secretions, studded with tubercles, ulcerated at some points, and gangrenous at others; the nose is occasionally nearly eaten away; and large cavities generally exist upon the cheeks. The frontal sinuses, larynx, and bronchial tubes are livid and excessively congested; and the lungs often contain abscesses, occupied by ill-elaborated matter, looking more like aplastic lymph than genuine pus. The heart is commonly softened. The mucous coat of the stomach and bowels is diminished in consistence, discolored, and sometimes studded with minute tubercles, similar to those observed in the nose. The pustules which exist beneath the skin and in the connective tissue among the muscles, bear a great resemblance, in the nature of their contents, to metastatic or multiple abscesses; they contain no true pus, at least not in their earlier stages, but a dense, solid, fibrinous matter, strikingly like that so generally found in pyemia and other forms of blood-poisoning.

The *diagnosis* of glanders is, in general, sufficiently easy. An inexperienced practitioner, deceived by the aching pains and soreness of the joints and limbs, might possibly mistake it in its earlier stages for rheumatism; but the occurrence of secondary symptoms would soon dispel the illusion. From the effects of a dissection wound it may readily be distinguished by the peculiar discharges from the nose, and by the character of the cutaneous eruption. The history of the case, too, will always furnish important diagnostic data. The fact that the patient has nursed or examined a glandered horse or person, will generally of itself afford strong presumptive proof of the true character of the attack. In the latter stages of the disease, the nasal discharges, the existence of pustules, abscesses, and gangrenous spots, and the horribly fetid exhalations from the body, are signs which it is impossible to mistake.

The character of the *prognosis* may be gathered, in great measure, from what precedes. The acute form of the disease is nearly always fatal. Of fifteen cases, collected by Rayer, only one recovered. The danger in chronic glanders, on the other hand, is much less. Thus, of ten cases, mentioned by the same writer, seven recovered and three died.

The *treatment* of this affection is preventive and curative. The former consists in the adoption of proper measures for destroying the poison as speedily as possible after the inoculation. With this view, the affected or abraded surface should be freely washed by holding it for a considerable length of time under a concentrated stream of water, and then thoroughly cauterized with acid nitrate of mercury, or some other active escharotic, or, what is better, effectually excised. If the operation is impracticable, and the wound is of a punctured nature, it should at once be enlarged, and then brought fully under the

influence of some caustic, otherwise a portion of the poison lurking deep in the wound may escape its contact, and thus be absorbed into the system. If a person is known to have died of glanders, the safest plan for the practitioner is to avoid a post-mortem examination, especially if there are any abrasions, however slight, upon his hands and fingers.

The curative treatment, if it deserve such a name, has hitherto been entirely unavailing. Bleeding, both local and general, purgatives, tonics, and stimulants have proved alike useless. Obviously our chief reliance must be upon the employment of supporting measures, especially quinine, carbonate of ammonium, tincture of chloride of iron, and brandy, given in large and frequently repeated doses, in combination with liberal quantities of morphia, with a view both of allaying pain and controlling gastric irritability. Infiltrated fluids and abscesses should be promptly evacuated, and the affected parts wrapped up in flannel wrung out of saturnine and anodyne lotions. The nose should be frequently injected with tepid water impregnated with creasote, carbolic acid, or tannate of iron; liquid chlorinated sodium freely sprinkled upon the body and bedclothes; the apartment constantly ventilated; and the utmost attention paid to cleanliness. To these means should be added, in chronic cases, change of air, or residence near the sea-coast.

5. WOUNDS INOCULATED WITH A PECULIAR SEPTIC POISON GENERATED IN DEAD ANIMAL BODIES.

a. *Dissection Wounds.*

Wounds contracted in the examination of dead human bodies are named dissection wounds, and are deserving of special attention on account of the severe effects which they are capable of producing. These injuries generally occur in the form of punctures, abrasions, or slight incisions, and would generally be altogether unimportant if it were not for the fact that they are often inoculated with a peculiar poison, septic in its character, and, therefore, liable, if absorbed, to contaminate both the part and system. The instruments with which they are usually inflicted are the scalpel, tenaculum, and needle, especially the latter, as it is very apt to prick the fingers in sewing up dead bodies. Not unfrequently, the inoculation is effected through the medium of a preëxisting abrasion, or scratch, of the presence of which the person may, at the time, be perfectly unconscious. It is not necessary, however, for the entrance of the virus that there should be an open wound or a denuded surface, experience having shown that it may find its way into the system through a hair follicle or even through unbroken skin, as when the hand is immersed for an unusual length of time in poisonous fluid, as, for example, during the dissection of a person dead of puerperal peritonitis.

Of the nature of the poison which produces these severe effects nothing whatever is known. It is supposed that it is generated a short time before death, during the act of dying, or soon after dissolution, and that its development is due to a vitiated state of the blood hitherto unexplained. The idea is certainly plausible, supported as it is by the circumstances that the poison is generally most virulent when it is communicated by persons dead of puerperal fever, erysipelas, carbuncle, phlebitis, pyemia, septicemia, carcinoma of the liver, and kindred affections. Punctures received in the examination of the bodies of persons who have died from strangulated hernia are peculiarly dangerous. Once formed, the poison, like the virus of chancre, becomes independent of its source. A proof of this fact was afforded me, some years ago, in the person of a young cutler, who, in sharpening a case of dissecting instruments for me, which had not been used for nearly five months, slightly pricked one of his fingers. The hand and arm soon became exceedingly painful, as well as a good deal swollen, a characteristically red line extending up as high as the axilla, the glands of which were also speedily involved in the disease. Nearly a month elapsed before he recovered from the immediate effects of the injury. A prick of the finger received in cleaning bones has sometimes been followed by severe suffering and even loss of life. It is generally supposed that a fresh body is more liable to convey the poison than one that has been kept for some time. This, however, is not always true; for in a subject which had been on hand for nearly a month, and which I dissected, in 1827, along with Dr. Temple, of Virginia, that gentleman came very near losing his life from a little puncture inflicted upon his thumb at the end of that period. It is worthy of remark that the body was that of an old woman, who had perished from the effects of tertiary syphilis, as was apparent from the extensive disease of the skull and other portions of the skeleton.

Violent effects sometimes follow the dressing of wounds, from the contact of foul and

irritating discharges, and a number instances are upon record of surgeons having lost their lives from this cause. Similar results occasionally occur during the removal of malignant growths from inoculation with the secretions of the affected structures. The health of Professor Dudley, of Lexington, suffered seriously for several years from the inoculation of his hand with the matter of an encephaloid sarcoma during the amputation of the patient's arm. Dr. Physick met with a case of death from the effects of a slight scratch with an oyster-shell. Bad effects not unfrequently follow punctured wounds caused by the fin of a fish, especially in persons of intemperate habits and of dilapidated constitution, although they are probably not of a poisoned character.

An accoucheur, a friend of mine, suffered very severely from the inoculation of two of his fingers with the juices of a decomposed child. In opening and extracting the head, he slightly scratched himself with the broken bones; in ten hours after the accident he was seized with a violent and protracted rigor, followed by vomiting and high fever; a red line soon extended up each arm as high as the axilla, and nearly a week elapsed before he regained his health sufficiently to be able to attend to business.

The period of *latency* of this poison is usually very brief, or, more properly speaking, only a short time elapses before the occurrence of well-marked symptoms; for it is extremely probable that it begins its peculiar operation upon the inoculated structures almost immediately after its introduction, although its explosive effects may not manifest themselves nearly so soon. Generally they do not come on before the end of the second day, or the commencement of the third. In one case—the most remarkable, in this respect, on record—very severe symptoms ensued within the first twelve hours, and the patient died in forty hours from the receipt of the wound. In the case of Dr. Temple, above alluded to, violent indisposition set in within less than thirty-five hours from the time of the inoculation. The accident happened late on a Saturday night, and on the following Monday morning he was taken so ill that he was obliged immediately to retire to his room, which he did not leave again for nearly two months. In the case of Kissam, a medical student, recorded by the late Dr. Godman, grave symptoms supervened in less than fifteen hours, although death did not occur until the fifth day. On the other hand, the patient occasionally remains free from suffering for a comparatively long period, as in the instance of Mr. Newby, an English surgeon, who, having received a puncture in opening the body of a child dead of enteritis, experienced no serious inconvenience until the commencement of the fourth day.

Some persons seem to be peculiarly liable to suffer from this poison. Thus, I, myself, seldom, in my younger days, while much engaged in post-mortem examinations, opened a dead body without the operation being followed by a boil upon my hand, thumb, or finger. Occasionally the consequences were more serious, the disease extending up the arm, along the course of the absorbents, as high as the axilla. Disordered health, hard study, general debility, mental anxiety, and other causes, no doubt, powerfully predispose to the development of the disease. A student who has for weeks inhaled the foul atmosphere of the dissecting room, taken little exercise, and sat up late at night, eating, perhaps, withal, very heartily, will be much more likely to contract the disease, and to suffer severely, if he be wounded, than one who has taken better care of himself.

Symptoms.—The usual point of departure of this disease is the inoculated part, from which it rapidly spreads in every direction. A smarting, stinging, or burning sensation is generally the first circumstance which attracts attention. Upon looking at the part, it is found to be covered with a little, whitish vesicle, perhaps hardly the size of an ordinary pin's head, filled with serum, and resting upon a hard, reddish base, extremely sensitive on pressure. When this vesicle breaks, as it usually does within the first twenty-four hours, a small ulcer is exposed, having a foul base, and discharging a thin, sanious fluid. The pain by this time is generally very distressing, burning, and pulsatile, depriving the patient of appetite and sleep; the sore enlarges; the swelling augments; and the part feels exceedingly hot, tense, heavy, and numb. Generally a red line is seen extending from the seat of the inoculation along the arm to the axilla, marking the course of one or more of the absorbent vessels. As the poisonous influence spreads, the whole limb becomes enormously enlarged, pitting on pressure, and exhibiting a dusky, erysipelatous appearance. With this increase of swelling there is a proportionate increase of pain, which now amounts to torture; the limb feels heavy, like a mass of lead, and is completely powerless. In bad cases the inflammation extends to the top of the shoulder, the axilla, and even to the corresponding side of the trunk.

Such is the ordinary course of the disease; but cases occur where the order of the symptoms is reversed, the poison exploding in the axilla, and thence extending up the

neck and down the side, the arm being, perhaps, almost free from inflammation, and there being no appearance, or only a very slight appearance, of disease at the seat of the inoculation. The swelling, which sometimes reaches as low as the crest of the ilium, is, at first, of a doughy character, and of a pale pink hue; but it soon becomes hard, and assumes the peculiar erysipelatous blush already described as belonging to the more common variety. The pain is generally exquisite from the beginning, and is sometimes of itself sufficient to crush the system, before sufficient time has elapsed for the formation of the distinctive pustule. Such cases, which are always fraught with danger, occasionally terminate fatally in a few days.

It is not every case of inoculated dissection wound that gives rise to general symptoms; on the contrary, in the great majority of instances the affection is entirely local, being confined to the immediate neighborhood of the original injury, diffused over the hand and wrist, or, it may be, limited to a few absorbent vessels, as indicated by the red lines extending up the limb. Under such circumstances the patient may feel a little unwell, have some headache, and want of appetite, or suffer from chilliness and aching of the limbs, but there is no serious disturbance of the general health. This will, however, be sure to occur if the virus has gained full admission into the system, the symptoms showing themselves, on an average, in from twelve to twenty-four hours. The patient, at first, has merely a feeling of depression, or faintness, with a sense of chilliness, pain in the head, and slight derangement of the digestive organs. This prodroma is speedily succeeded by violent rigors, alternating with flushes of heat, by nausea and vomiting, excessive restlessness, intense thirst, an increase of cephalalgia, a haggard, woebegone state of the countenance, and indescribable despondency. The tongue is coated, the respiration hurried, the skin dry and hot, the pulse sharp and frequent, but feeble. The bowels are either constipated, or, as more frequently happens, harassed with diarrhœa.

The disease, in its worst forms, soon reaches its crisis, the system rapidly falling into a typhoid state. During this downward course the symptoms above described become more and more marked; the tongue is dry and brown; the pulse quick and tremulous; the countenance sallow and withered; the skin yellow and covered with clammy sweat; and the suffering indescribably severe. Delirium always sets in at an early period, and is a prominent symptom throughout. Death occurs in a few days to a few weeks, according as there is overwhelming exhaustion, or depression from gangrene and metastatic abscesses.

The appearances discovered on *dissection* are variable. When the case has run its course very rapidly, the internal organs may, apparently, be entirely free from disease, or there may be evidence of slight effusion into the chest, with an engorged condition of the lungs, the affected structures themselves being somewhat infiltrated with serum and lymph. Under opposite circumstances, there will generally be marks of inflammation of the arachnoid membrane, pleura, lungs, and peritoneum, with, perhaps, deposits of pus in the larger joints, among the muscles, and in the subcutaneous connective tissue. The parts more immediately involved in the morbid action will be found to be enormously distended with the ordinary products of inflammation, highly softened at some points and greatly indurated at others, with, here and there, an abscess, and, perhaps, a gangrenous spot.

The *prognosis* of this affection may be deduced, in some degree, from the preceding remarks. When the disease is strictly local, much suffering may be the consequence, but ultimate recovery will be certain, the part immediately affected becoming, perhaps, withered and completely useless, as often happens when the lesion is seated in a finger. In the very worst cases death may occur in less than forty-eight hours, apparently from the empoisoned condition of the nervous system, with little or no evidence whatever of local disease. In another class of cases, also very bad, the patient may live five or six days, and then perish from the violence of the resulting inflammation; or he may linger for weeks and months, abscess after abscess forming in the limb, on the side, or in other regions of the body, and finally die from constitutional irritation; or, lastly, he may, after having been for a long time on the very brink of the grave, struggle through the disease, and in the end make a good recovery, or he may remain permanently weak, and crippled in some internal organ.

Some persons are a long while in recovering from apparently very trifling accidents of this kind, depending either upon some idiosyncrasy, or upon some derangement of the general health. I myself formerly suffered a great deal in this way. On one occasion my thumb, accidentally pricked in examining the body of a woman dead of phthisis, remained sore for fifteen months; and a former colleague of mine, Professor

Rogers, of Louisville, had an affection of this kind upon one of his fingers which troubled him for upwards of three years. When the disease is thus protracted, the probability is that disorder of the digestive organs is essentially concerned in nursing its latent embers.

Treatment.—The treatment is preventive and curative. As soon as a wound of this kind has been received, the part should be most thoroughly washed with warm water and Castile soap, and then subjected to a stream of cold water, followed by suction performed with the mouth. If the wound be very small, or valvular, the best plan will be to dilate it, as a preliminary step, in order to facilitate the extraction of the poison. Whatever method be adopted, the operation is completed by effectual cauterization with acid nitrate of mercury, inserted into the wound by means of a small, pointed stick of wood. In the absence of this article, which I prefer to everything else for the purpose, use may be made of nitrate of silver, butter of antimony, hydrochloric, nitric, or sulphuric acid, or a saturated solution of equal parts of alum and nitre. Persons who habitually suffer from dissection wounds should always employ some precautionary measures in examining dead bodies, such as anointing the hands well with pomatum, lard, tallow, or simple cerate, and even wearing thin leather gloves, any fluids that may be present being previously removed by an assistant. Fortunately, since the introduction of chloride of zinc injections, now in common use in our schools, inoculation in any form from dissection wounds is much less frequent than formerly. In the Jefferson Medical College, no case of a serious character has occurred since this article was first employed by Professor Wallace. The pupils of the other institutions of this city have, I believe, been equally exempt.

If the case has been neglected, or if, despite the above precautions, a vesicle forms at the site of the wound, a free incision should at once be made, when, bleeding having been encouraged by immersion in warm water, the part should be thoroughly cauterized with nitrate of silver, or brushed over with dilute tincture of iodine, an ectrotic effect being still hoped for, although not likely to be attained. Warm water-dressing with laudanum is then applied, and a brisk cathartic administered, the patient being kept strictly at rest upon light diet and carefully watched. If the disease extend, means must be employed to limit its action, and to sustain the system. In view of the inevitable typhoid tendency, all exhausting remedies must be scrupulously withheld, especially the lancet and active purgation. If nausea and vomiting are present, a mustard and salt emetic, or an emetic of ipecacuanha, is administered, and the bowels and secretions are regulated by mercurial laxatives, aided, if there be high fever, by tepid sponging of the surface, and the use of the neutral mixture. To relieve the excessive pain and restlessness, morphia must be given in large and sustained doses, united, if the skin be hot and dry, with aconite or veratrum viride. The distressing headache so often attendant upon the disease, must be treated with cold applications, the hot foot-bath, and the exclusion of light and noise; but anodynes generally afford more ease than anything else. If inflammation of the arachnoid be threatened, a few leeches may be applied to the temple, or a blister to the nape of the neck. To meet the typhoid symptoms milk punch, quinine, iron, and ammonia are indispensably necessary. In the more terrible forms of the disease, commencing with violent pain in the axilla, side, and shoulder, these means should be used at once, in large quantity, especially the brandy, with the hope of neutralizing the poison, and thus arresting its zymotic tendency. Although we know nothing of the nature of this poison, it is not at all improbable, judging from the good effects which attend the employment of alcohol in the treatment of snake-bite, that brandy and other spirituous liquors might be of great service in dissection wounds. The suggestion, at any rate, seems to me to be worthy of attention. Their beneficial effects might possibly be increased by the free use of carbonate of ammonium; certainly by that of anodynes.

As it respects the parts more immediately concerned in the disease, the best application, after the first ten or twelve hours, is warm water-dressing, medicated with laudanum and Goulard's extract, acetate of lead, or chloride of ammonium, preceded and accompanied by dilute tincture of iodine. Lint wet with oil of turpentine and laudanum sometimes affords great comfort. Blisters and nitrate of silver are objectionable, their vesicating effects interfering with other remedies. Leeches are occasionally productive of great relief, but they are not to be used, except in very robust subjects, and in the earlier stages of the affection. When there is much œdema, the pressure of the bandage will be useful. Tension is relieved, and matter evacuated, by free and timely incisions.

Covering the parts thickly with strong mercurial ointment, along the whole track of

the inflamed lymphatic vessels, is sometimes useful in arresting the spread of the morbid action, and promoting the absorption of effused fluids. Professor Wallace speaks in high terms of this mode of treatment, which is especially worthy of trial in the earlier stages of the disease.

The secondary effects of this class of injuries yield most readily to change of air, attention to the secretions, and the use of tonics, iodide of potassium, and cod-liver oil. In obstinate cases, a mild course of mercury may be necessary. The most eligible topical remedies are evaporating spirituous lotions, or solutions of acetate of lead, Goulard's extract, or chloride of ammonium. Sometimes a deep and free incision will afford more prompt relief than anything else.

Finally, it must not be forgotten that students and physicians who spend much of their time in the dissecting-room, in the dead-house, or in making post-mortem examinations in private families, are not fit to attend women in their confinement, or to dress wounds, compound fractures and dislocations, or to perform surgical operations, however simple, without previously subjecting themselves to thorough ablutions with disinfecting fluids and even, in many cases, changing their clothing. The finger nails, in particular, should be thoroughly cleansed, otherwise inoculable matter may readily be conveyed to healthy persons.

b. *Malignant Pustule.*

This is a disease, primarily, of the cutaneous and connective tissues, commencing in the form of a little vesicle, and rapidly terminating in gangrene, its cause being a septic virus generated by horned cattle laboring under murrain. The French surgeons usually describe it under the name of charbon, and in many parts of Europe it is vulgarly known by the term Persian fire, or malignant pimple, the former having reference to the horrible pain which attends it, the latter to its destructive tendency.

The disease is met with in various sections of the Union, although it appears to be less common here than in Europe. Cases of it have occasionally been noticed in this city and its vicinity, and I have myself seen it in Kentucky, where, as well as in Ohio, Illinois, Tennessee, Mississippi, and Louisiana, murrain sometimes prevails as an epidemic. In the latter State it caused great havoc in the summer of 1851, among the stock of the parishes of St. Mary and Vermillion, carrying off an immense number of cattle, as well as a considerable number of horses and mules, among the latter of which it first broke out. Hogs and dogs that ate of the carcasses took the distemper, and soon died of it. Several cases occurred in which the disease was communicated to the human subject by the green carrion-fly. During my residence at Louisville, four cases of the malady, all contracted in flaying and eviscerating cows dead of murrain, came under my observation.

In Europe, malignant pustule has hitherto been chiefly observed on the continent, particularly in France, Holland, Switzerland, Germany, and Russia. It is also very common in Siberia and South America. The inhabitants of Great Britain appear to be nearly exempt from it. In France it is most common in Lorraine, Franche-compté, Burgundy, Province, Lyonnais, and some of the other southern regions. It is rare at Paris, but frequent at Marseilles, showing that locality is favorable to its production.

The disease is most common upon the hands and face, because these parts, being habitually exposed, are most liable to inoculation. Persons who work among hides, both green and dry, tanners, butchers, shepherds, blacksmiths, and veterinary surgeons, are most liable to its attacks. It is often contracted by the common people in flaying and eviscerating animals dead of murrain. It has also occurred from introducing the hand into the rectum and vagina of cows laboring under putrid fever. The virus has occasionally been conveyed by insects from diseased brutes to man. I have already alluded to the fact that it may be communicated by the green carrion-fly. It would seem that certain parts of an animal, as the hair and wool, retain the poisonous matter for a long time, and even after they have been most thoroughly washed and cleansed. Dr. Bourgeois refers to an instance in which the disease was apparently produced by picking the horsehair taken out of an old sofa; and of eight cases reported, in 1868, by Dr. G. E. Stone, of Massachusetts, all, except one, occurred in workmen, women, or children engaged in the manufacture of curled hair. A very common way in which it is contracted is in handling dry hides. Even tanned leather is said to be capable of communicating the affection. It has been conjectured that it might be contracted by eating the flesh of brutes dead of murrain, but there are no facts that justify such a conclusion. Whether it can be conveyed from one human being to another, or from man to the inferior animals, is also undetermined.

What the nature of the *poison* is which produces this disease, or when, where, or how

it is developed, is a question which we have no means of solving. It is evidently of a zymotic character, like the virus of smallpox and chancre, and is generated by most of the domestic animals, especially cattle dead of murrain, its occurrence being less frequent in the horse, mule, ass, and sheep. It is also probable that it may be generated by birds, as the hen and turkey. In a case, of which I have collected the particulars, the disease was contracted by three persons in picking and eviscerating several buzzards with a view of extracting their oil. Both the hands and forearms of each individual were inoculated. Violent local and constitutional symptoms showed themselves by the end of the second day after the operation, the parts being excessively swollen and painful, and covered with numerous vesicles, which, upon bursting, exposed ill-looking ulcers, discharging a thin, sanious fluid, and remaining open for many weeks. The inflammation reached up to the axilla, the glands of which were enormously enlarged, some of them finally suppurating. Recovery took place only after a long time, and after great suffering, reducing the patients to the utmost degree of exhaustion. It is difficult to say whether, in these instances, the poison was actually generated by these birds, or merely conveyed by them through their feathers inoculated by carrion.

Dr. Davaine, in 1863, advanced the idea, based upon personal observation, that this disease is communicated exclusively through the agency of bacteria, which are found in the blood and lymph of the vesicles of diseased animals, and some recent investigations would seem to corroborate this view. The bacteria consist of very minute, slender filaments, cylindrical, straight, stiff, detached, devoid of motion, and capable of successive and indefinite transmission from the pustule of charbon by inoculation so long as the blood and solids retain their vitality.

Symptoms.—The period of latency of the disease is very brief, generally, perhaps, not exceeding a few hours. The first distinguishable evidence of the operation of the poison is a small reddish point, not larger than a pin's head, and the seat of a burning, itching sensation, attended with a desire to scratch. Gradually spreading in size, it is speedily followed by a little vesicle, filled with a thin, turbid serum, which, in its turn, is soon replaced by a pustule of a yellowish, brownish, or reddish color, according as it contains pure pus, or pus mixed with blood. Around the pustule is a distinct areola, not unlike that of smallpox; the part is exquisitely painful, hard, circumscribed, and easily lifted from the adjacent structures. Continuing to extend, it becomes gradually more and more prominent, until it acquires a base equal to the diameter of a twenty-five cent piece, a half-dollar, or even a dollar, and is surrounded by a zone of œdema. Meanwhile the pustule bursts, revealing a foul, gangrenous ulcer, discharging a sanious, fetid, irritating fluid, sometimes quite abundant. Long before the disease has reached this crisis, the affected limb is enormously swollen, stiff, numb, heavy, and exquisitely painful, the inflammation often reaching as far as the shoulder, and seriously involving the axillary glands. The number of vesicles is variable; in one of my cases there was only a single one: in another there were two, one on the hand and the other on the forearm; in the third there were five; and in a fourth the whole arm and hand were literally covered with them, their number amounting to several hundred. When numerous, they are always proportionately small, not exceeding the diameter of a currant or a split pea.

When the disease is seated in the face, the swelling is generally so great as to give rise to the most hideous distortion, and to render it almost impossible to distinguish one feature from another. The eyelids are closed and distended like bladders, the lips are several times their natural thickness and hardly movable, the cheeks are enormously puffed out, and the natural line of demarcation between the jaw and neck is completely obliterated. The face, in fact, looks more like a dark, shapeless mass than a human countenance. When seated here, the malady is apt to extend to the throat, causing great swelling of the palate and tonsils, attended with intense difficulty of deglutition and respiration, sometimes followed by suffocation.

The constitutional symptoms are those, in the first instance, of general malaise, or uneasiness, with a feeling of depression and foreboding of evil. Presently high fever sets in, preceded and accompanied by rigors; after which, in a very short time, the patient sinks into a low, typhoid condition, commonly attended with muttering delirium, loss of sleep, and excessive restlessness. Death often follows in three or four days from the first manifestation of the disease; but sometimes it does not take place under a week, and in rare cases not before the end of a fortnight. The patient's habits and state of health at the time of the inoculation, the quantity of matter absorbed into the system, and the nature of the treatment, all, doubtless, exercise an important influence upon the issue of the

case. As a general rule, however, it may be stated that few recoveries occur under any circumstances.

Dissection has hitherto thrown no light upon the nature of this disease. The internal organs, especially the lungs, are generally considerably engorged ; and in a few instances metastatic abscesses have been found. The affected limb is usually distended with serum and lymph, the latter of which often exists in large quantity, giving the parts their characteristic hardness, and exhibiting occasionally, here and there, a greenish, gelatinous appearance. In one case I discovered several depots of blood. If the patient survive sufficiently long, abscesses may form in the subcutaneous connective tissue, and probably even in some of the viscera, especially the lungs and liver. The inflammation seldom extends deeply among the muscles, its progress being, apparently, limited by the aponeuroses. The axillary glands are sometimes much enlarged, softened, discolored, and infiltrated with various kinds of fluids. In the immediate neighborhood of the vesicles the parts are of extreme density, cutting with a grating noise very much like fibrocartilage. Doubtless the veins and absorbents are implicated in the disease, but in what manner, or degree, has not been ascertained. There is usually, after death, a tendency to rapid decomposition.

Treatment.—The treatment is prophylactic and curative. As soon as it is ascertained that an individual has been inoculated, the part should be cut out, after which it should be well washed with warm water, to encourage vascular disgorgement, and then still further drained by the cupping glass, these means being followed by thorough cauterization with dilute acid nitrate of mercury or solid nitrate of silver. Or, instead of this, the part is destroyed with the Vienna paste, or the hot iron. When the pustule is fully formed it should be excised or destroyed ; the zone of induration should be incised and thoroughly cauterized ; and the zone of œdema, as recommended by Verneuil, should be injected with ten drops of a one-half per cent. solution of iodine. When early and effectual riddance has been neglected, or found impracticable, the treatment must be conducted upon general principles, by mild, soothing, and supporting measures. All sanguineous depletion, both by the lancet and leeches, active purgation, and other debilitating means, are avoided, as calculated, inevitably, to hasten the fatal crisis. The secretions, always seriously deranged in this disease, are rectified by small doses of calomel, the excessive pain is allayed by morphia, and the system is sustained by the liberal use of brandy, quinine, and other stimulants. The limb, placed in an easy, elevated position, is wrapped up in light flannel cloths, wrung out of a tepid solution of lead and opium, tension and throbbing being relieved by early and free incisions. Sometimes great comfort is experienced from the employment of an emollient cataplasm, covered with laudanum and olive oil. Fetor is allayed by the chlorides, which may also sometimes be advantageously given internally. During convalescence, the cure must be promoted by nutritious food, and change of air. The most efficient disinfectants of poisoned commercial hair, hides, and other articles are sulphuric acid and a moist temperature at from 140° to 150° Fahr.

CHAPTER XI

RAILWAY INJURIES.

RAILWAY injuries present so many points of interest, and differ, withal, so much from other lesions, as to demand special notice in a work of this kind. Indeed, the differences between such injuries and ordinary wounds are quite as striking as the differences between the latter and gunshot wounds, or the gunshot wounds of the present day as compared with those of former times, prior to the invention of the conical ball. Moreover, lesions of this kind are worthy of particular study, not less so on account of the frequency of their occurrence than the frightful mortality that attends them. In this country alone, where, in 1882, there are nearly 100,000 miles of railway, the loss of life, in one form or another, from these accidents, is absolutely appalling, the number of persons destroyed by them amounting annually to several thousand, while the number of those permanently maimed is vastly greater.

The lesions in railway accidents may be caused by the passage of the wheel of the carriage, by the pressure of the buffer, or by fragments of broken timber entering the

body, cutting, lacerating, and contusing the tissues, perforating the joints, and laying open the viscera. The most frightful shocks and concussions are generally caused by railway collisions, in which the passengers are thrown forcibly from their seats against such objects as may happen at the moment to be near them, the violence of the injury being generally in proportion to the speed of the train. Frightful accidents, attended with excessive injury of the soft parts and the bones, as well as extreme shock, placing limb and life in jeopardy, are of frequent occurrence from the passage of the wheels of street cars.

Railway injuries may, like injuries from other causes, be limited exclusively to the soft parts, or, as is most generally the case, they may involve both these structures and the bones, the latter, indeed, often suffering in a far greater degree than the former. In extent they may be slight, on the one hand, or, on the other, so severe as to prove fatal, either instantaneously, without any attempt at reaction, or secondarily, as the result of inflammation and its consequences. In their character they may simply exhibit the features of a contusion, or they may occur in the form of a wound, either open or subcutaneous, most generally the former, contusion and laceration preponderating. Beside these peculiarities, railway injuries are further distinguished from the more ordinary lesions by excessive shock and concussion of the nervous system, by the small amount of hemorrhage, by the impossibility of procuring union by the first intention, by the frequent necessity of amputation, and by the great liability to erysipelas, pyemia, and osteomyelitis ; all concurring to impart to these accidents distinctive features.

These lesions may be grouped, according to their effects, under different heads : 1st. Cases that are instantaneously fatal, or that soon become fatal, either from shock and concussion, or from the combined influence of shock and hemorrhage ; 2dly. Cases in which reaction occurs, followed by recovery, or by death from exhaustion, inflammation, erysipelas, or pyemia ; 3dly. Cases of incomplete recovery, some parts remaining permanently incapacitated ; 4thly. Cases in which remote effects, as epilepsy, hysteria, paralysis, loss of memory, morbid sensibility, or insanity, manifest themselves, perhaps not until a number of months or even several years after the infliction of the primary injury.

1st. In the worst forms of railway injury, death may be due solely to the violent concussion, not of the nervous system merely, but of the entire body, every organ and tissue feeling its baneful influence. In such a condition there may perhaps not be any outward evidence of injury, not even, it may be, a scratch upon the skin, although generally the injury sustained both by the soft parts and the bones is very great. In some of the more severe cases, the local injury is associated with extensive rupture of the capillary vessels. Thus, in one recorded by Mr. Hill, numerous vascular points, the size of a pin's head, and, here and there, minute clots, existed in the muscles of the head, chest, and abdomen, as well as in the brain, heart, lungs, liver, spleen, and kidneys. The blood, under such circumstances, is of a semifluid, black appearance, very much as in death from lightning. In fact, the whole train of morbid phenomena is such as clearly shows that death was occasioned by the sudden, total abstraction of nerve fluid. Such accidents find their counterpart in injuries caused by falls from a great height, as a tree or a scaffold, producing death instantaneously by concussion of the whole body.

Excessive shock is often conjoined with more or less serious hemorrhage. The largest bleeding usually occurs in injuries of the extremities, attended with laceration of the principal vessels, as the femoral, popliteal, or tibial arteries and veins ; but, now and then, as in railway lesions of the chest or abdomen, large quantities of blood may be poured out into the splanchnic cavities, thus greatly complicating the case, and rendering it more surely fatal.

Intense shock, rapidly terminating in death, may result from injury of a single organ, as the brain, heart, or lung, the rest having in great degree escaped. Such accidents find their counterpart in death from a blow or kick on the stomach. Or, the viscera may be free from injury, and the fatal shock be due solely to the extensive lesion sustained by the external parts, as those, for instance, of the lower extremity, the skin, muscles, vessels, and nerves being mashed and pulpified, the large joints torn open, and the bones crushed and ground to powder.

2dly. Shock, although very violent, is often followed by reaction, even when there is very grave injury, in the same manner as in concussion of the brain from falls and blows on the head. In the generality of cases, the reaction is slow, twelve, twenty-four, or even forty-eight hours elapsing before it is fully established, the system frequently faltering in the interval even under the sustained employment of the most powerful stimulants. Or, the reaction, after various efforts, at length fails, and fatal collapse ensues. Some

times the system rallies sufficiently to admit of the removal of the injured structures by the knife, the patient, if there has been much shock or loss of blood, either dying under the operation or soon after; or, if he survive the immediate effects, standing a fair chance of perishing from fever, erysipelas, or pyemia. Experience has proved that amputations performed for severe railway injuries afford a very high rate of mortality, far greater, indeed, than after almost any other class of lesions, those made by the round ball not excepted. The stump, in such cases, is not unfrequently assailed by erysipelas, osteomyelitis, or even gangrene, the disease either causing death or necessitating further operative interference.

If an attempt be made to preserve the injured structures, the surgeon will run great risk of losing his patient by the violence of the resulting fever, erysipelas, gangrene, septicemia, pyemia, or profuse suppuration, death generally supervening within the first five, eight, or ten days. Railway wounds never unite by the first intention; and in most cases, even when the contusion and laceration are comparatively slight, some degree of sloughing is almost inevitable.

The symptoms of shock in railway accidents do not differ from those of shock produced by ordinary causes. When the accident has been uncommonly severe, as when a man is knocked down by a train in rapid motion, the patient is frightfully collapsed, the pulse and breathing are hardly perceptible, the countenance is of a deadly pallor, the pupils are widely dilated, and the surface of the body is covered with cold sweat. These symptoms often exist when there is no evidence whatever of local injury.

3dly. Incomplete recovery after railroad accidents is of very frequent occurrence, and may manifest itself in a great variety of ways, depending upon the nature of the injury and the character of the organs or structures involved. Thus, special sensation is often impaired in accidents involving the base of the brain, as shown in the loss of the sense of smell, taste, sight, or hearing. Paralysis of an arm or of a leg, or even of one side of the body, may be caused by a severe wrench or twist of the spine, eventuating in direct pressure by displaced bone, or indirect pressure by effusion of blood. Atrophy of a part of a limb, or even of an entire limb, is by no means uncommon; sometimes a joint is permanently disabled; and contraction of the muscles and tendons may be mentioned as another effect that properly falls under this head. The speech is occasionally considerably impaired, being weak and indistinct; and various anomalous symptoms are often present, as confusion of ideas, a sense of cold or of unnatural heat about the head, inability to attend to business, a pinched expression of the face, and a withered condition of the whole body. Occasionally, especially after injuries of certain nerves, there is a feeling of numbness, of formication, or of pricking, as if pins and needles were moved about in the parts. These and similar effects may be the sequences of the slightest as well as of the most violent injuries.

4thly. Remote effects, coming on at a variable period after the primary, not unfrequently follow upon railway accidents. These effects manifest themselves in various degrees as well as in various forms; sometimes in one manner, and sometimes in another, from the slightest departure from the normal condition of an organ to the complete perversion of its functions. The exciting cause is more commonly a slight than a severe one, the patient, after having suffered from shock, having, perhaps, made a rapid recovery, or so nearly regained his mental and physical vigor as to be able in a short time to resume his accustomed occupation as if nothing had happened to him. By and by, however, generally after the lapse of several months, without any assignable cause, his general health gives way, or he gradually loses his control over some particular organ. The approaches denotive of these occurrences are usually very stealthy and insidious, and hence, long before the patient is made fully sensible of their import, the most serious pathological changes may take place at the seat of the original lesion; changes which, if correctly interpreted at the time, might have easily been prevented, but which, now that they have acquired the ascendency, may lead to fatal, or, if not to fatal, to permanently ill consequences. Most of these remote effects are referable to injuries of the nervous system, more especially to those of the spinal cord and of the base of the brain, manifesting themselves in various forms of functional derangement and in impairment of the circulation and nutrition either of the entire body or of some particular part.

Among the more common and distressing of these remote effects are various uneasy sensations in the head, as a feeling of numbness, dizziness, weight, and tension, as if a hoop were firmly stretched around it. Occasionally there are shooting pains, or pains seated at some particular spot, more or less tender on pressure; a throbbing feeling is not uncommon; various kinds of noises are complained of; the mind is peevish and irritable;

the ideas are confused; the sleep is disturbed by harassing dreams; volitional power, mental and physical, is greatly at fault; the patient is often very emotional, frequently bursting into tears, and he is unable to apply himself to business, the slightest effort of the kind being attended with an aggravation of suffering. The organs of the special senses are frequently affected, as is evinced by the impairment of the function of smell, hearing, taste, and sight. The speech is rarely much, if at all, involved. Marked strabismus occasionally exists. The countenance has a contracted appearance, and an uneasy expression, the person often looking much older than he actually is, or than he did before he was hurt. The pulse is generally small, and somewhat above the numerical standard; the breathing is short and abnormally frequent; the digestive organs are deranged, the appetite being irregular, and the taste more or less vitiated; the bowels are constipated, and, as assimilation is impaired, the patient loses weight and strength. The kidneys and the bladder usually act naturally, but the sexual functions are often very deeply implicated, and in some cases the individual is completely impotent. Paralysis often exists, more generally in the inferior than in the upper extremities, sometimes on one side and at other times on both; in various degrees, from slight failure of motor power to total loss, occasionally associated with defective sensation, and usually coexistent with loss of temperature and clammy perspiration. In many cases the loss of power is confined to special muscles and tendons, which, in consequence, soon become permanently shortened and contracted, leaving the patient in a weak, tottering condition, and extremely liable to fall. More or less wasting of the affected limb generally occurs, amounting occasionally, in the more advanced stages of the complaint, to the most degraded atrophy. Among the more uncommon of the remote occurrences after railway accidents may be mentioned mental imbecility, epilepsy, and insanity, coming on, perhaps, at the end of several years, long after the patient had apparently completely recovered from the immediate effects of the injury.

It is generally very difficult, if not impossible, to refer these effects to their true sources; it is reasonable, however, to suppose that in the great majority of cases they are essentially due to changes effected in the cineritious substance of the cerebro-spinal axis by inflammatory irritation. Occasionally the immediate cause undoubtedly is an effusion of plasma, or of this material and of serum, of serum alone, or of blood, either in a fluid or solid state, poured out at the time of the accident, remaining unabsorbed, and by its pressure interfering with the transmission of the nerve current.

The prognosis in these secondary affections must necessarily depend upon the circumstances of each individual case. If, after they have remained stationary for some time, or if, after various fluctuations and changes, there is a gradual but decided improvement in the symptoms and the general condition of the patient, strong hopes may be entertained of ultimate restoration; the progress to health must, however, necessarily be slow, and it will be well, in order to guard against disappointment, to look for occasional interruptions. Now and then a case occurs in which the improvement is steady and persistent. The prognosis may be considered as unfavorable when there is a progressive increase of the local distress along with a gradual failure of the general health, the more especially when the downward tendency is due to great involvement of the cerebro-spinal axis, as indicated by loss of muscular power and perverted sensation. As it respects the continuance of life, the patient may last for many years, and eventually die of some intercurrent disease.

In the *treatment* of railway injuries four distinct indications are presented: to relieve shock, to arrest hemorrhage, to prevent undue inflammation, and to guard against the occurrence of secondary effects.

In the treatment of shock the same general rules are to be observed as in shock from any other cause; the usual management being by recumbency, cold water, sinapisms, the smelling-bottle, stimulating injections, and, if the patient can swallow, by the exhibition of brandy and ammonia. Overaction is prevented by morphia and the neutral mixture in conjunction with veratrum viride and other suitable measures.

Hemorrhage is controlled by ligature, torsion, acupressure, and styptics. Any wound that may exist is dressed and treated in the usual manner. If the injury occupy an extremity, and is so excessive as to demand amputation, the operation should be performed as soon as reaction has been sufficiently established to enable the patient to bear the shock and loss of blood, the limb being always removed some distance beyond the apparent seat of the lesion, lest some of the bruised and lacerated tissues being left, gangrene may seize upon the stump. If the system has only partially rallied, anæsthetics should be dispensed with, the knife then often acting as a salutary stimulus, favoring reaction and increasing the chances of recovery.

Inflammation must be limited by the usual means, opium being freely given to control the heart's action, to tranquillize the system, and to promote sleep; the secretions are corrected with blue mass; and the heat of the skin is allayed by mild diaphoretics, and by sponging the surface frequently with tepid water containing a little alcohol and vinegar. Quinine and tincture of iron are freely administered, if there has been much loss of blood; cooling drinks are used; the temperature of the room is properly regulated; and milk punch, beef essence, and the different kinds of broths are relied upon to sustain the system.

Convalescence is carefully watched, any untoward occurrence being promptly met by appropriate measures. Local irritation is combated by leeches and blisters, aided by rest and elevation of the affected part. Bodily and mental excitement must be avoided, the bowels and secretions duly attended to, and the diet properly regulated. Involvement of the lungs and other internal organs must be guarded against by more than ordinary vigilance. If secondary effects ensue, a mild course of mercury will be indicated, the remedy in many cases being advantageously given in union with iodide of potassium. Slight ptyalism, steadily maintained for several consecutive weeks, is sometimes required. In these chronic affections great benefit is often derived from the use of the cold shower-bath, change of air, mild tonics, and the judicious application of electricity.

CHAPTER XII.

EFFECTS OF INJURIES UPON THE NERVOUS SYSTEM.

Under this head may be considered the more immediate effects of injuries, as nervous depression, or shock, and, as it has not inaptly been termed, traumatic delirium. These effects may succeed to almost any lesion, however trivial or complicated, their production being greatly influenced by the temperament, habits, age, and idiosyncrasy of the individual; and they deserve the most careful study, inasmuch as they are frequently followed by the worst consequences. The subject of tetanus might properly be included under the present division, but as this disease occasionally arises without any external injury, the discussion of it will be postponed until I come to speak of the affections of the nerves.

SECT. 1.—PROSTRATION, COLLAPSE, OR SHOCK.

Shock is a depression of the vital powers, induced suddenly by external injury, and essentially dependent upon reflex paralysis of the entire circulatory system, but especially of the heart and abdominal vessels. It bears, in effect, the same relation to the nervous system as syncope to the vascular; in the one case the result is caused by inhibition of the vasomotor centres, in the other by a diminution of blood; in both, the consequence is more or less prostration, with perturbation of mind and body, extremely variable both as to intensity and duration. When the nervous shock is severe, it may instantaneously terminate in death, as so often happens in falls and blows upon the head; more generally, however, after having continued for an indefinite period, it passes into reaction, the powers of life gradually coming up, as the different organs and the general system regain their nervous fluid. The most severe and fatal cases of shock are generally those that supervene upon direct injury to the great nervous centres, as the brain and spinal cord; no less disastrous effects occasionally succeed blows upon the epigastric region, in consequence of the violence thus inflicted upon the solar plexus of nerves. In some of these and similar instances life is destroyed with the same rapidity as by lightning, the nervous fluid being instantaneously annihilated without the individual being rendered conscious of his doom. Such cases have their counterpart in those frightful hemorrhages in which, a large artery, as, for example, the aorta, being divided, the patient perishes in a few seconds from loss of blood. The blood is a vital fluid, the integrity of which is indispensably necessary to the well-being of the system and the maintenance of healthy action. But it is certainly not the only fluid entitled to this distinction; the nervous fluid is both more subtle and more important as a life preserver. When blood flows away in a mighty and overwhelming torrent, the person dies, and life is then said to be destroyed, as it certainly

is, by the excessive sanguineous drainage. But in shock, the same effect may happen, and yet the body be literally surcharged with blood, not a single drop, perhaps, having been spilled in the accident causing the fatal result. Thus, of the two fluids, the nervous is, in every respect, the more important, because the more essential to life; and its disturbance is, therefore, a more frequent cause of death.

Shock may be produced by a great variety of *causes*, some of a bodily, others of a mental, character; some external, others internal. It may be purely nervous, or partly nervous and partly hemorrhagic, that is, dependent upon the conjoined loss of the nervous and sanguineous fluids. The nature and extent of shock are greatly influenced by the state of the general health at the time of the accident, the amount of the injury, the importance of the part more directly assailed, and, also, in an especial manner, by the idiosyncrasy of the individual. There are some persons, soldiers, for example, of the most undoubted courage, men who would not hesitate to face the mouth of the cannon, who fall into a state of the most profound prostration from the most trifling accident; who turn pale and tremble like a leaf; whose minds are perfectly bewildered, and who are, as it were, completely stunned, from injuries so insignificant as not to effect, in the slightest degree, ordinary persons. Such an occurrence can only be explained by a reference to idiosyncrasy; and it has its counterpart in those persons who, although extremely plethoric, faint from the slightest loss of blood, or even from the mere sight of that fluid. There are other persons, on the contrary, whom hardly any accident, however severe, can shock; they are insensible to pain; their nervous system is obtuse; nothing affects them, either bodily or mentally; a severe blow may stun them, but the impression is transient; in a few minutes they are completely restored to consciousness and power. Here, again, is an example of idiosyncrasy, a peculiarity of organization; in the former case, the individual is all nerve, all sensibility; in the latter, all blood, all muscle. But it is not only the nervous and irritable that suffer from shock; the fat and corpulent are prone to be affected by it from the slightest causes, and hence such persons seldom make good subjects for the knife; they bear the loss of blood badly, and are extremely liable to perish from erysipelas and pyemia, in consequence, as it appears to me, rather of loss of nervous fluid than from any toxic state of the blood, or blood-poisoning, properly so called. There are some individuals whom the slightest operation will kill; touch them, and they are sure to die; they are destitute of life power, and incapable of resisting the slightest shock. The fainting produced by the pricking of a needle and the introduction of a bougie affords a familiar illustration of shock from trivial causes.

Among the external causes of shock deserving of particular notice, on account of their crushing effects, are injuries of the skull and spine, such, for example, as are produced by a fall or blow; gunshot, railway, steamboat, and factory wounds; dislocations and fractures; violent sprains, burns, and scalds; and some of the more severe operations, as the extirpation of enormous tumors, and the amputation of the larger limbs, even when not attended with any considerable hemorrhage. The extraction of a tooth, in a very nervous person, has been known to occasion fatal shock.

Severe shock is frequently produced by internal causes. One of the most familiar examples of this kind is afforded in perforation of the bowel, consequent upon typhoid fever, and followed by extravasation of fecal matter. The moment this takes place, the shock is immense; if the patient had been struck severely on the head, it could not be more so; in some cases it is so overwhelming as to destroy life in a few hours. The pain which attends the passage of a gall-stone, or of a renal concretion, is often followed by similar results; extravasation of urine may be mentioned as another illustration. Many a woman has perished from shock induced by severe labor; and the excessive prostration consequent upon apopleptic seizures is familiar to every practitioner.

The occurrence of shock is more or less influenced by the state of the system. Whatever undermines the vital powers renders the system less capable of resisting an effect of this kind, and should be duly considered in weighing the prognosis after a severe injury, or the probable consequences of a severe or protracted operation. Shock is never borne well by persons laboring under organic disease of the heart, liver, or kidneys, and for this reason they are, as a rule, unfit subjects for the knife. Children and old persons suffer, other things being equal, more disastrously from shock than persons in the prime and vigor of life. General debility, intemperance, anemia, and debauchery of any kind exercise an unfavorable influence, and often sadly interfere with reaction. The location of an injury often exercises a remarkable influence upon the degree and duration of shock. Compound fractures and dislocations and gunshot lesions of the splanchnic cavity and of their contents are often followed by severe and long-continued, if not overwhelming

shock ; but of all depressing effects of this kind, and the one most surely fatal is that consequent upon extensive scalds and bruises, in which the collapse is widespread and complete, often unattended even by the faintest possible show at reaction.

Mental shock is often extremely severe, and is occasionally followed by the worst consequences, especially when it occurs during the progress of a severe illness, or after a severe surgical operation. Fright is perhaps the very worst of the causes of mental shock. The effect of terror, in suddenly exhausting nervous power, is well illustrated by the history of those persons, who, sentenced to be bled to death, actually died on hearing water trickling into the basin, which they supposed to be blood issuing from their veins, after the arm had been slightly pricked, although no vessel had been opened. It is related of Desault that he one day lost a patient, about to be lithotomized, from sheer fright. The man, who was very cowardly, fainted and died under the impression that the operation was progressing, when this distinguished surgeon was, in fact, only tracing with his nail the line of the intended lesion on the perineum. A sick, bedridden person, in danger of being burnt to death, has been known to perish from shock brought on by excessive mental trepidation. The receipt of disagreeable news, the sudden loss of property, and, in short, violent mental emotion of almost any kind, may give rise to similar effects.

Mental and corporeal shock are often combined ; and it is then not uncommon to see the former preponderate, in a very marked degree, over the latter. The soldier on the field of battle may suffer from bodily shock induced by a severe wound ; he may feel that he is badly hurt, but still he is sanguine of recovery, and cheerfully and manfully bears up under his affliction. The surgeon examines his wound, and, perceiving its grave character, informs him that it will probably cost him his life. Instantly the case assumes a different aspect ; the system is overwhelmed with perturbation and excitement ; the vital powers are depressed to the utmost ; and death takes place, perhaps, several days sooner than it would otherwise have done. In railway accidents, caused by the collision of the cars, this combination of mental and physical shock frequently exists in an astonishing degree, sometimes affecting large numbers of persons simultaneously. Here the shock is the result evidently not of mere concussion of the cerebro-spinal axis, but of the whole body and mind as well.

The *symptoms* of shock, although extremely variable, are generally such as attend syncope from loss of blood, or concussion of the brain, which is itself only a form of nervous depression, or expenditure of the vital forces. If the accident has been slight, the effect will be that of a moderate stun, that is, the patient will experience some degree of mental confusion, look pale, and feel weak and tremulous ; objects will appear dark to him, and he will probably reel, if not fall. Presently, however, especially if he lies down, reaction will take place, and in a short time he will recover both his mental and physical powers, so as to be able to converse, act, and walk in the same manner as before he was hurt. When the injury has been severe, the effect upon the nervous system will, of course, be proportionately greater. The patient, unable to support himself, falls to the ground, often, as he does so, inflicting serious violence upon his person. Consciousness, special sensation, and volition are, perhaps, completely abolished ; the countenance is deadly pale ; the respiration is slow and feeble ; the pulse is small, fluttering, and, at times, altogether imperceptible ; the extremities become rapidly cold ; and the surface is soon bathed with an abundant, clammy sweat. Gasping and sighing, with convulsive tremors, are often present, generally but too clearly denoting the serious character of the lesion. Not unfrequently there are involuntary discharges from the bowels, with nausea and even vomiting.

The duration of these symptoms is subject to no little diversity ; at times they pass off in a few minutes, or, at furthest, in a few hours ; at other times they last for several days, and even then, perhaps, they do not disappear entirely, one or more persisting for a considerably longer period. When the shock is very severe, death may occur instantaneously, or the case may linger for some time in a state of doubt and uncertainty, with, now and then, an attempt at reaction, and at last prove fatal. Instances occasionally occur in which, after tolerably complete reaction has been established, the system sinks again into a partial state of collapse, the vital forces evidently having not sufficient stamina to maintain the functions of the brain and heart. Such cases are very liable to end fatally, generally within the first twenty-four hours after their occurrence.

Reaction, after shock, is denoted by a gradual, or more or less rapid, resumption of the functions of the different organs, which awake, so to speak, from their slumber, and spring back again into life and happiness. One of the first evidences of this change is a return of the color of the face, with an increase of the heart's action, as indicated by the state

of the pulse, which is not only stronger and fuller, but more steady and regular ; the respiration is more free and open ; the surface becomes warmer and dryer ; the sphincters again obey the will ; and the mind regains its self-possession and power of action. Often the first symptom of reaction, after severe shock, is vomiting, followed by complete clearance of the contents of the stomach, itself generally a favorable sign, as it is often denotive of a return of muscular power.

There is a form of shock which has been, not inaptly, called insidious, as the symptoms are generally of a masked character, and are, therefore, well calculated to deceive both the patient and practitioner. The person, although severely injured, congratulates himself upon having made an excellent escape, and imagines that he is not only in no danger, but that he will soon be about again ; in fact, to look at him, one would hardly suppose, at first sight, that there was anything serious the matter ; the countenance appears well, the breathing is good, the pulse is but little affected, except that it is too soft and frequent, and the mind, calm and collected, possesses its wonted vigor, the patient asking and answering questions very much as in health. But a more careful examination soon serves to show that deep mischief is lurking in the system ; that the machinery of life has been rudely unhinged, and that the whole system is profoundly shocked ; in a word, that the nervous fluid has been exhausted, and that there is not enough power in the constitution to reproduce and maintain it. The skin of such a person assumes an icterode, or sallow, cadaverous appearance, feeling at the same time doughy and inelastic ; the extremities are deadly cold ; the pulse makes a desperate effort at reaction, but is, at best, weak and tremulous ; there is little or no pain ; and the patient is altogether too composed and tranquil for one who has sustained such an amount of violence. The system does not seem to be conscious of what has occurred ; its sensibilities are blunted, and it is incapable of suffering. Nature, to use the language of Hunter, does not feel the injury.

The countenance, in this form of shock, has often a peculiarly, melancholy expression, as if foreshadowing the fatal event ; a sad smile plays upon the lips, and illumines the lower part of the face, while the upper part wears a gloomy aspect, in striking contrast with the other. The forehead, as the patient looks at his attendants, especially if he has just been roused from sleep, is strongly knit and wrinkled, giving it a scowling and sinister air. As the case progresses, the brain gradually sinks into a comatose condition, the signs of prostration become more pronounced, and death finally occurs from mere exhaustion, life seldom lasting longer than three or four days.

The *treatment* of shock must be conducted with two objects in view, to promote reaction, and to moderate supervening inflammation, for to prevent it altogether is by no means always possible.

A patient affected with shock should immediately be placed recumbently, all constriction should be removed from his person, free access of cold air should be provided, cold water should be dashed upon the face, smelling-bottles should be passed to and fro under the nose, and sinapisms should be applied to the extremities and to the precordial region. If the case is unusually severe, with a decidedly downward tendency, atropia or tincture of digitalis should be injected under the skin, stimulating injections should be thrown into the rectum, and turpentine rubbed along the spine. If deglutition is practicable, brandy and water should be given, but in trying to convey these or any other fluids into the stomach, great care must be taken, otherwise they may descend into the windpipe, and so cause strangulation. The most prudent plan, in such a condition, is to introduce the drink with a spoon, the mouth being previously forced open, and a powerful effort made to excite the patient's attention by hollowing loudly into his ears. If he cannot swallow, no attempt should be made at compulsion, but, for the reasons just mentioned, the effort should at once be discontinued. Stimulants, especially alcoholic, should never be given in large quantities at a time. Teaspoonful doses, administered every five, ten, or fifteen minutes, are, as a rule, much more efficacious and reliable than larger quantities, the only effect of which, at least in many cases, is to add still further to the depression of the system, and, consequently, to render reaction more difficult, if not impracticable. The hypodermic injection of a fourth of a grain of morphia occasionally greatly promotes respiration.

In the milder cases of shock, the most simple treatment often suffices to bring about reaction, as the recumbent posture, a drink of cold water, and the use of the fan and smelling-bottle. The blood and nervous fluid soon resume their wonted channels, and the vital forces rapidly regain their supremacy.

In the mental form of shock, a soothing word, or an assurance of the absence of danger, often goes further in promptly effecting restoration than the most powerful stimulants, steadily and regularly administered. Persons suffering from this variety of prostration

are frequently much more frightened than hurt, and promptly regain their animation and self-possession on being told that their injuries are altogether of a simple, trivial character, devoid of all danger, both present and future.

Occasionally reaction is sadly interfered with by an overloaded and oppressed stomach, as when the accident occurs soon after a hearty meal. In such cases, the patient often lies in a state of deadly pallor, with more or less retching, for hours, before he can shake off the oppressive burden. The indication obviously is to assist nature in her efforts at emesis, by the administration of a dose of alum, ipecacuanha, or sulphate or zinc, or, what, perhaps, is better, under such circumstances, equal parts of common salt and mustard, or mustard alone. Serious lesion of the brain is hardly to be considered as a contraindication to such a course, when it is recollected that the digestive powers are completely suspended, and with what difficulty reaction takes place when the stomach is oppressed by a heavy meal.

The silly and reprehensible practice of bleeding persons laboring under the exhaustion of shock, once so common, has happily become obsolete. No surgeon should do anything without a reason, and it is, therefore, difficult to perceive what could ever have induced a procedure so contrary both to physiology and common sense. In the opinion of the vulgar, there are no cases in which it is not proper, immediately after such an accident, to draw blood from the arm; but assuredly no practitioner would yield his judgment to such an erroneous view, and perform an operation that might speedily prove destructive to his patient. Fortunately, whenever such an attempt is made by the ignorant and thoughtless charlatan, the blood generally refuses to flow, and consequently no harm is done.

The second indication is to moderate the resulting inflammation. To do this, much may be accomplised, in the way of prevention, by letting on the reaction gradually; avoiding, on the one hand, the undue use of stimulants, and, on the other, cautiously interposing antiphlogistics as occasion may arise for their exhibition. Proper allowance is made for the apparent violence of the symptoms, the excitement without power; the struggle may be furious, but will in all likelihood be brief, for, if the previous depression has been at all severe, the flame will ere long cease of its own accord, or readily yield to the influence of very simple means. such, for instance, as sponging the surface frequently with cool or tepid water, and administering a little morphia and antimony, aided by rigid abstinence, and perfect tranquillity of mind and body. Bleeding should be practised only in young and plethoric subjects, with a tendency to serious inflammation of some important internal organ, and where, consequently, the fire is real, not feigned. The opposite course often exerts a most pernicious influence upon the patient's recovery; impairing his vital powers, and preventing the system from keeping up a due supply of healthy nervous fluid, so conducive to the restoration both of the part and system. As the secretions are commonly materially deranged in all cases of severe shock, early and effectual means should be adopted for their correction and improvement; a gentle mercurial purge will often admirably fulfil the indication, and render any further use of this class of remedies unnecessary. The diet for the first few days should consist mainly of animal broths, conjoined, if necessary, with milk punch, or wine whey, and cautiously followed by food of a solid and more substantial character. Starvation, in cases of severe shock, is not to be thought of. Such a course cannot be too pointedly or too forcibly condemned, as it is contrary alike to sound sense and the dictates of an enlightened experience.

Anodynes are always borne well after severe shock, and should be administered early and freely, to allay vascular action and tranquillize the nervous system. The most suitable article is morphia, or the ammoniated tincture of opium, either alone or conjoined with valerian, the latter remedy being especially serviceable in nervous, hysterical persons, or what is far better, bromide of potassium. If the vital powers sensibly flag after the occurrence of reaction, recourse must be had, in addition to anodynes, to quinine, carbonate of ammonium, and brandy, liberally and diligently administered. Determination to internal organs is met by leeches, blisters, and other counterirritants.

SECT. II.—TRAUMATIC DELIRIUM.

One of the most unpleasant effects with which the surgeon has to contend in the treatment of wounds and other injuries, as well as after surgical operations, is the occurrence of delirium, at a period too, perhaps, when everything is apparently progressing in the most favorable and gratifying manner. All of a sudden, the nature of the case undergoes a remarkable change for the worse; the horizon, just a moment before perfectly calm and serene, like a summer's sky, is almost instantly overcast by a dark, lowering cloud;

the system is thrown into nervous tremors, and the mind, agitated with disagreeable forebodings, is absorbed in some peculiar fancy, in which the patient imagines himself pursued by his enemies, or annoyed by persons peeping at him through the keyhole of his door, making grimaces at him through the window, or concerting measures for his destruction. Great diversity obtains in respect to the manner in which the disease is ushered in. In some cases the symptoms are apparently of a hysterical character, the patient laughing and talking in a loud, boisterous, and incoherent manner; or perhaps indulging in unmeaning jokes about the nature of his disease, the manner in which he was hurt, or the conduct which he exhibited during the operation he has undergone. In another class of cases, by no means uncommon, he is completely absorbed in his business; he harnesses his horses, hitches them to the carriage, and swears at them because they do not move to please him. In some cases, again, he is seized with a species of religious frenzy; he prays and sings, and utters pious exclamations. Occasionally, he labors under some demoniacal delusion; he fancies that the devil has possession of him, and that he is about to be carried to the infernal regions. Finally, there are instances in which the patient is sadly annoyed by the idea that he is pursued by snakes, dogs, or rats, or that some horrible reptile is trying to creep into his throat. In short, there is no end to these delusions, which are often as ludicrous to the observer as they are distressing to the patient, to whom they are always a source of severe suffering, not less so than if they were real.

The cause of these symptoms is not always apparent. In the great majority of cases, they are produced, either directly or indirectly, by the inordinate use of alcoholic spirits, suddenly interrupted by the occurrence of a severe injury, attended, it may be, by dreadful shock or copious hemorrhage, thus greatly increasing the susceptibility of the nervous system to external and internal impressions. It is not necessary for their development that the individual should have been an habitual drunkard; they often show themselves nearly as readily if he has merely been a free drinker without having carried the use of liquor to the extent of intoxication. On the other hand, they occasionally occur in persons of the most temperate habits, who have, perhaps, never used alcohol in any form, or for any purpose whatever. Dupuytren, who first called attention to this variety of the disease, has given it the name of nervous delirium, and in the paper which he published on the subject he has reported a number of cases in which it supervened upon various kinds of injuries and operations, some of them of a very trivial character, or such as usually produce no unpleasant results of any description, the patient rapidly recovering from their effects. It cannot be doubted that, in these cases, the affection is generally of a purely nervous nature, arising from the effects of the commotion inflicted upon a delicate and highly susceptible constitution. Under such circumstances, it is often mixed up with the effects of shock, rendering it difficult, if not impossible, to distinguish them accurately from each other. All practical surgeons have frequent opportunities of witnessing such cases. So far as my observation extends, I am not aware that any class of injuries is entirely exempt from the disease; sometimes the most trivial scratch or contusion is followed by it. Corpulent persons, who generally bear injuries and operations very badly, are particularly liable to this form of delirium. Burns and scalds, railway lesions, lacerated wounds, and compound fractures may be enumerated as among the more powerful causes of the affection. It has been thought that children are less liable to suffer from nervous delirium than adults and elderly subjects, but this is certainly not true; on the contrary, such is the susceptibility of the system at this tender age to physical and mental impressions that the slightest accident is often sufficient to develop it. If women are less frequently affected than men, it is simply because they are less exposed to the various exciting causes of the disease. There is certainly every other reason why they should suffer quite as much as men, if indeed not more.

Nervous delirium generally comes on within the first twenty-four or forty-eight hours after the application of the exciting cause: it may last for a variable period, but rarely longer than five or six days, and may terminate either in health or in death, according to the gravity of the injury that has produced it. Its leading symptoms are a confused, wandering, or flighty state of the mind, with excessive vigilance; incoherency of speech and manner; absence of fever; an open, moist state of the skin; and little or no excitement of the pulse. The eyes have generally a wild expression, and the patient is easily disturbed by noise and light; as well as by the presence of his attendants. The appetite is usually impaired, the bowels are costive, the urine is scanty and rather high-colored, and the feet are disposed to be cold. If the patient be spoken to, he is generally readily roused, but soon lapses into his former condition.

Nervous delirium properly so called, is easily distinguished from delirium tremens by the

absence of tremors, which form such a striking feature in the latter disease as to be characteristic. In delirium tremens the limbs are always in a tremulous condition; the symptom comes on early in the attack, and generally lasts until the effects of the disease are nearly worn off. When the delirium is fully developed, the hands and fingers are incessantly in motion, the patient carrying them to his mouth, face, and head, as if he were desirous of swallowing something, or removing some imaginary object from his person. The countenance is usually flushed, the eyes are deeply injected, the pulse is small, frequent, and quick, and the mind is roused with difficulty. Added to these circumstances is the history of the case, which generally affords valuable, if not conclusive, information respecting the patient's habits prior to his attack.

Delirium tremens, the result of alcoholic stimulation, is an extremely common occurrence after all severe operations and injuries, and is one of the most serious causes of their mortality. Hence operations should never, if possible, be performed upon this class of persons so long as they can be put off, or without due preparation of the system; special care should also be taken to avoid shock and loss of blood, as these are two of the most predisposing causes of the disease.

It is well known that persons addicted to the immoderate use of opium and tobacco are liable to suffer from a peculiar form of nervous delirium after severe injuries and operations, characterized by excessive wakefulness, and a sense of indescribable wretchedness, with a bewildered and confused state of the mind, from which it is sometimes extremely difficult to rouse them, so as to induce them to take their necessary food and medicine. It is not improbable that the excessive use of coffee and tea may, in persons of a very nervous, excitable temperament, produce similar effects.

As was previously intimated, traumatic delirium usually sets in at an early period after the application of the external injury that provokes it; sometimes, however, the patient, perhaps contrary to expectation, goes on exceedingly well for some considerable time, happily surmounting the primary effects but suffering severely from the secondary, the consequence commonly of profuse, unhealthy, and exhausting suppuration. Again, instances occur in which he may have several attacks of this nervous suffering, with a variable interval of several days to several weeks, during which the mind may be perfectly clear and tranquil, the patient bearing up manfully under his disorders, sanguinely and fully anticipating none other than the most favorable termination.

Traumatic delirium, however induced, or in whatever manner it may present itself, is often extremely difficult of management. In its worst forms, the mind is frequently so completely disordered as to render confinement of the patients with the strait-waistcoat an indispensable element of the treatment. This is the more necessary when, as sometimes happens, the patient is disposed to tear off the dressings from his wounds, to commit suicide, or to hurt his attendants and nurses. There is a remarkable circumstance which has been noticed by all practitioners in this class of persons; I allude to their utter indifference to pain. So great is this, in many instances, that they will not only uncover their wounds, but absolutely take pleasure in handling and picking them. Dupuytren refers to the case of an old man who, having been operated upon for strangulated hernia, tore away the dressings from his groin, and composedly squeezed his bowels, his friends all the while thinking he was getting on most admirably, such was his calm and quiet demeanor as he lay in bed.

One of the most important indications, then, is to set a careful watch over the patient, in order that he may not do any harm either to himself or others; in wounds and fractures the most perfect quietude is generally necessary, and the greatest pains should, therefore, be taken to secure it to the fullest extent, for whatever has a tendency to disturb and fret the parts will be sure to act as a cause of additional excitement. Moral force alone will be of no avail; the patient can neither reason correctly himself, nor comprehend the arguments of those about him. Hence, if medicine does not promptly effect the object, the only resource is the strait jacket, applied of course with proper care, so that, while, on the one hand, it shall not be so loose as to frustrate the intention of its use, it shall not, on the other, be so tight as to occasion injurious constriction; a circumstance which, although a matter of paramount importance, is not always, as I well know from experience, so scrupulously attended to as it should be by nurses and practitioners.

The next indication is to tranquillize the nervous system, and induce sleep, or, in other words, to get rid of the redundant excitement. To fulfil this indication, anodynes must be administered in such doses as shall most promptly and effectually bring about the desired result. The patient must sleep before he can obtain relief; the early interposition, therefore, or suitable treatment is a matter of primary moment, attacking and routing

the disease, as it were, in its very incipiency, ere yet it has taken firm hold of the system. The most trustworthy and unexceptionable remedies are bromide of potassium and hydrate of chloral, in the proportion of twenty to thirty grains of the former to ten, fifteen, or twenty of the latter, repeated every two or three hours, until tranquil and refreshing sleep ensues. Of all the remedies that I have ever employed in the treatment of this class of cases, none have proved so speedily and permanently successful as these; and the great advantage which they possess over opium is that they do not cause nausea, constipation, headache, or, in short, any of the unpleasant effects which so often follow the exhibition of the latter article. There are, however, cases in which opium, either in the form of morphia or of the acetated tincture, in moderate and sustained doses, may be given with great advantage, especially if it be combined with tartar emetic. The latter remedy is particularly valuable when there is much vascular excitement, on account of its tendency to relax the system and promote perspiration. In the milder cases, the disease often promptly yields under the influence of a small quantity of laudanum, as from fifteen to twenty-five drops, in half an ounce of camphor-water and a drachm of compound tincture of cardamom, repeated every two or three hours. Dupuytren was in the habit of employing laudanum as an injection in this disease, giving from ten to twenty drops with a small quantity of water, and frequently repeating the dose, until he succeeded in accomplishing his purpose. The medicine thus administered often exerts, he declares, a much more prompt and happy effect than when taken by the mouth; and the result of my own experience amply corroborates the truth of the statement. As a preliminary measure, the rectum should be well cleared with an ordinary enema.

When opium and its preparations cannot be borne, an excellent substitute will occasionally be found in hyoscyamus, lupulin, aconite, belladonna, or Indian hemp; aided by the cool shower-bath, followed by dry frictions, or, what will generally answer quite as well, and be more convenient, sponging of the surface freely and repeatedly with tepid, cool, or cold water. When the delirium is furious, leeches should be applied to the temples, or a large blister to the nape of the neck, and cold to the scalp, previously divested of hair. As a temporary expedient, and as an auxiliary for allaying the violence of the spasms, the judicious inhalation of chloroform may be of service. General bleeding will not be proper in any case, whether of nervous delirium or delirium tremens, unless there is excessive plethora, with marked determination to the brain. In nervous, hysterical females, the free use of assafoetida and of valerianate of ammonia often produces a very happy effect.

When the patient has been an habitual drunkard, or when the delirium can be distinctly traced to the effects of the sudden withdrawal of alcoholic stimulation, the dictates of common sense, not less than the results of sound experience, indicate the propriety of a resumption of the accustomed drink, or a resort to an appropriate substitute. Much judgment will, of course, be necessary under such circumstances, lest the remedy be carried too far, causing thereby additional excitement and vigilance instead of composure and refreshing sleep. Nutritious food taken in small quantities, and frequently repeated, is generally very beneficial, the best articles being milk, beef essence, animal soup, and raw eggs beaten up with milk. When a mild stimulant is required there is hardly anything so reliable as a mixture of essence of brandy and catchup, or an infusion of capsicum. In most cases a good supply of nourishment is indispensably necessary to a cure. The bowels must not be neglected. A large dose of calomel, when there is much disorder of the secretions, given at the commencement of the disease, often excercises a powerful influence in quieting the nervous system and controlling morbid action. Vomiting, not unfrequently a prominent symptom, is most effectually relieved with the neutral mixture, champagne, and pounded ice. Sometimes a mustard emetic acts like a charm.

CHAPTER XIII.

GENERAL DIAGNOSIS.

DIAGNOSIS is the art of distinguishing and identifying diseases and accidents, or, in other words, of determining their seat, nature, and effects. Its study is of paramount importance to every practitioner, and he should, therefore, omit no opportunity of improving his knowledge of it. Its value, practically considered, has been felicitously expressed by Louis, the illustrious secretary of the French Academy of Surgery. "The science of diagnosis," says he, "holds the highest rank among the different branches of the healing art, as it is at once the most useful and the most difficult. The discernment of the peculiar character of each kind of disease and of its different species constitutes the source of all curative indications. Without a clear and exact diagnosis, theory must always be at fault, and practice frequently uncertain." It is by his knowledge of diagnosis that the practitioner acquires a command over disease which he who is destitute of it can never attain. It should, therefore, form the great object of his inquiry in every case of disease and accident; for to be able to locate and define their seat and character is almost to be able to cure them. To be incapable of doing this, is literally to grope in the dark; or to toss to and fro, like a mariner without a helm, upon an ocean of uncertainty. To disentangle truth from error; to give to disease " a local habitation and a name;" to distinguish one injury from another; and to base upon the knowledge thus derived a rational and scientific course of treatment, calculated to restore the sufferer to comfort and health, are among the highest attributes of the practitioner, and require an amount of talent, tact, and experience such as few men possess. " Know what ails the patient and he is already half cured," is a Chinese aphorism affirmable in almost every instance.

The very first thing that a surgeon should do when he is called to a case of disease is to set up an inquiry into its true nature; to ascertain where it is situated, or what structures it involves; how it has been brought about; what progress it has made; and what are its essential characteristics, or in what particulars it differs from other lesions. In order to do this with any tolerable degree of success, it is necessary, in many cases, literally to interrogate every important organ and tissue of the body, with a view of ascertaining which of them are more directly implicated in the disorder, which are free from suffering, and which are affected only sympathetically. Such a step is generally indispensable when the lesion is of spontaneous origin, or when it arises without any appreciable cause. When the converse is the case, a less elaborate examination will usually suffice to supply the requisite light. Not unfrequently the nature of the complaint is perceived at a glance.

SECT. I.—EXAMINATION OF THE PATIENT.

To examine a patient well, so as to elicit all the light that may be necessary to a thorough comprehension of the nature of his malady, requires generally great tact and an extensive knowledge of morbid and healthy anatomy, physiology, pathology, and animal chemistry, not to say anything of microscopy, now so much employed as a means of diagnosis. Any one may make a superficial investigation, and in the more ordinary cases such a mode of procedure may perhaps be all that is required; but under opposite circumstances, where everything is shrouded in obscurity, nothing short of the most patient and elaborate exploration will usually answer the purpose. Knowledge and tact alone, however, will not insure success; they may go very far, it is true, in enabling the practitioner to solve the mysteries of a case, but unless they are aided by a nice faculty of observation, and by a just sense of discrimination, he will never be able to analyze and group the facts presented to him in such a manner as to render them fully available when he comes to apply his therapeutic agents. Unfortunately, however, the power of observation is a rare gift, which few possess, and still fewer use to advantage. Surgeons, like physicians, have eyes, but they do not always see, and ears, but they do not always hear. Another

fault, of which, unfortunately, too many, even among the most sagacious and best informed, are frequently guilty, is the hasty manner in which examinations are made ; and, hence, it is no wonder that so many disgraceful and fatal blunders are daily committed by men who, if they would only allow themselves proper time, might see disease as clearly as if they were looking at it in a mirror. Hasty examinations commonly lead to hasty deductions, as hasty deductions do to hasty generalization and slovenly practice. All practitioners do not, of course, require the same amount of time to arrive at a correct judgment respecting the diagnosis of their cases ; some literally jump at conclusions ; others reach them only by a slow and tedious process of investigation and induction. Of the two, the latter are generally the safer practitioners.

The object of an examination is often seriously interfered with, if not entirely frustrated, by the want of coöperation of the patient, in consequence of his timidity, his want of intelligence, or the perverseness of his disposition. Much adroitness is, therefore, often required to bring out the desired result ; fully as much as the lawyer is obliged to expend in the examination of a witness who is incapable of appreciating the responsibility of his position, or of making a proper use of his knowledge. To gain the confidence of a patient is one of the first duties of a practitioner, as this is often necessary not only to a full development of the history of his case, but to its successful management. A gentle word, an agreeable tone, a winning manner, are well calculated to effect this result, and are, practically considered, attributes of the highest value. " To question fitly," says Rousseau, " is the art of a master." The examination should always be conducted with the greatest delicacy ; no unnecessary exposure should be made ; and great care should be taken to guard against fatigue, especially when the patient is exhausted by disease, shock, or loss of blood.

Age, occupation, climate, and habits of life, being so many circumstances calculated to modify morbid action, should be among the first objects of inquiry at the bedside of the sick. There are many diseases which occur only at particular periods of life. Thus, scrofula is most common in children, scirrhus in elderly persons, chronic enlargement of the prostate in advanced age. The influence of occupation in the production of disease is well shown in hemorrhoids, varix, and ulcers of the legs, and, to go no further, in necrosis of the lower jaw in persons engaged in the manufacture of lucifer matches. Gout, rheumatism, pneumonia, and pleurisy are most common in northern latitudes, while dysentery, hepatitis, and fever are most frequent in southern. Individuals of dissipated habits are particularly prone to erysipelas, boils, and carbuncles, and are often attacked with delirium tremens when they become the subjects of severe injuries, as lacerated wounds, fractures, and dislocations.

Particular inquiry should be made into the previous history of the case ; whether there is any hereditary predisposition to disease ; whether the suffering organ was ever similarly affected ; how the present attack came on, how long it has been in progress, and what have been its chief symptoms. A careful examination of this kind cannot fail to elicit important and valuable information, which, if properly applied, may go far in saving the patient's life, or in cutting short his disease.

A knowledge of the causes of diseases often throws valuable light upon their diagnosis. Thus, the knowledge that a youth affected with urethritis recently had connection with a lewd female, at once leads to a proper comprehension of the nature of the case ; and in the same manner important aid may be obtained in deciding between a specific and a non-specific ulcer on the head of the penis. The diagnosis of a malignant pustule upon the hand is generally determined at a glance by a surgeon of experience ; but one of an opposite character will hardly arrive at such a result without being told that the patient a few days previously was engaged in flaying a diseased ox, or in handling green hides. During the existence of endemic and epidemic diseases, all persons brought within their influence are liable to their attacks, and the similarity of their symptoms is consequently sufficient to stamp their character. The knowledge that pyemia frequently follows upon severe injuries and capital operations is of the greatest value to the practitioner, as it enables him at once to interpret correctly the symptoms which attend that peculiar affection, the nature of which was so long a mystery.

In accidents, a knowledge of the manner of their occurrence is often a matter of great moment in a diagnostic point of view. Thus, if a man, in the act of falling from a considerable height, has alighted upon the vertex, and is immediately rendered insensible, and particularly if he remains in that condition for a long time, the inference is strong that the base of the skull is fractured, and that he will perish from the effects of the lesion, although there may be no apparent injury upon the portion of the head which re-

ceived the blow.   In railway accidents the leg may be severely hurt, and yet not sufficiently so to account for the extraordinary depression of the system ; inquiry discloses the fact that the body was violently compressed between the car and a post, and a more thorough exploration leads to the discovery of a rupture of the spleen, liver, bowel, or bladder; a circumstance which at once establishes the diagnosis, and prevents the patient from being subjected to useless amputation.

When the patient is unconscious, whether from disease or accident, valuable information respecting the nature of the affection may often be obtained from his nurses and friends ; or, in the latter case, from the by-standers, who thus become important witnesses of what transpired at the moment in regard to the manner in which the injury was inflicted, the previous state of the intellect, and the condition of the person immediately consequent upon the receipt of the lesion.

In the more obscure cases of diseases and accidents, the diagnosis can be arrived at only after the most patient, thorough, and systematic examination, a random exploration being worse than useless.   Every organ must be questioned, and even then it will often be extremely difficult to determine what the lesion really is.   In my own examinations I usually begin with the alimentary canal, from which I pass, successively, to the abdominal and pelvic viscera, the lungs and their envelops, the heart, brain, and spinal cord, and, finally, the external surface, carefully noting everything of importance as I proceed.   In this manner, it is difficult for any serious disease to escape detection, if the practitioner is at all endowed with the faculty of correct observation.

EXAMINATION OF THE DIFFERENT ORGANS.

DIGESTIVE ORGANS.—Very useful diagnostic information is generally afforded by the state of the tongue in surgical affections.   In traumatic fever, abscesses, rheumatism, and gout, the organ is unnaturally dry, and covered with a thick, white fur, at the same time that its tip and edges are abnormally red.   A narrow, pointed, or accuminated appearance of the tongue is also frequently observed under these circumstances, especially in young subjects.   In profuse hemorrhages, the tongue is generally very pallid, soft, flabby, and indented at the edges.   A dry, brownish, and tremulous state of the organ, with difficulty of protrusion, is generally denotive of the existence of a typhoid condition of the system, and, in connection with other symptoms of exhaustion, is to be regarded as an unfavorable occurrence.   It is the kind of tongue which commonly attends gangrene, malignant erysipelas, and the latter stages of traumatic fever.

The appearances of the tongue sometimes afford useful hints respecting the state of the digestive apparatus, and even of the general system.   Thus, aphthæ upon this organ, or small ulcers scattered over its surface, are usually denotive of chronic gastric disorder, or derangement of the stomach and liver, by correcting which the disease promptly vanishes. In constitutional syphilis, the existence of mucous tubercles upon the tongue affords at once a satisfactory solution of the nature of the complaint.   The presence of an excavated ulcer upon this organ, or upon the tonsils, with a copper-colored border and a foul bottom, is generally equally diagnostic of a contaminated state of the system.

A thick and tumid upper lip is generally denotive of a scrofulous taint of the system, or of a vitiated state of the alimentary canal, depending upon the presence of worms, and disorder of the hepatic and follicular secretions.   A cracked, chapped, or fissured state of the lower lip is often an accompaniment of general plethora, overfeeding, and gastroenteric derangement.   A pale prolabium is indicative of a deficiency of the coloring matter of the blood, and of the necessity of tonics.

Useful information is sometimes derived from an examination of the gums.   A red, spongy, and tumid state of these structures is usually denotive of a scorbutic diathesis, especially if it be conjoined with frequent bleeding and hemorrhagic spots in different parts of the body.   An eroded appearance is indicative of an accumulation of tartar or of caries of the teeth, while the presence of sordes is expressive of a typhoid condition of the system.

Pain in the throat and difficulty of deglutition are evidences of tonsillitis, and of disease or mechanical obstruction of the œsophagus.   A careful inspection of the fauces and the introduction of the probang usually readily determine the precise locality of the affection, as well as its nature.   In the former case, the tongue is carefully depressed with the handle of a spoon, or a tongue-holder, the mouth being widely opened as the patient sits upon a chair in a strong light ; in the latter, the surgeon, standing behind the patient, whose head rests against his chest, carries the instrument gently and cautiously along the tube until it comes in contact with the obstruction, which is not passed all at once, or

forcibly, lest undue violence should be inflicted, perhaps eventuating in rupture, inflammation, or ulceration of the œsophagus.

No examination in any case of disease, if at all serious, whether surgical or medical, can be considered as complete without a thorough exploration of the condition of the stomach and bowels. When it is recollected that disorder of the secretions of these organs, the presence of irritating ingesta, or the accumulation of fecal matter, is frequently a source of disease in other parts of the body, as well as in these organs themselves, the importance of an attentive examination of them cannot be too much insisted upon. The insertion of the finger into the rectum, and the use of the speculum, often lead to the most useful knowledge of the condition of the anus and lower bowel. An examination of the alvine evacuations not unfrequently reveals important information in regard to the state of the liver, as the presence, absence, or quality of the bile, and the action of the mucous follicles of the alimentary tube, and should never be omitted in any case of serious disease or accident.

Intellect.—The intelligence is often remarkably altered in disease and accident. Delirium and incoherency are common effects of all lesions attended with high arterial excitement. Their character, degree, and duration vary much in different cases, and are greatly influenced by surrounding and intrinsic circumstances, as the nature of our treatment, the intensity of the morbid action, the importance of the affected organ, and probably also by the idiosyncrasy of the individual. In general, as they are of a purely sympathetic character, they rapidly disappear with the excitement that induced them; coming and going, perhaps, several times in the twenty-four hours, especially during the vesperal and nocturnal exacerbations which are so liable to distinguish most febrile attacks, whether traumatic or idiopathic.

In organic disease of the brain and its envelops, on the contrary, a different order of things usually occurs. Here the delirium, once fairly begun, continues uninterruptedly, although it may be characterized by intervals of remission; and, as the morbid action progresses, it generally lapses into stupor, and this, ere long, into deep coma, which is but too often the immediate forerunner of dissolution. In compression of the brain, whether from extravasated blood, excessive congestion of the cerebral vessels, effusion of serum, or depression of the cranial bones, the intelligence is commonly completely abolished; the patient is deprived of all sensation and volition, and cannot be roused by the most powerful stimulants. He is, in fact, a mere automaton, dead to all surrounding impressions. If, from any cause, inflammation of the brain or of its membranes arise, the face soon becomes flushed, the eye suffused, the pupil contracted and impatient of light, the skin hot and dry, and the pulse quick, hard, and frequent. Delirium soon sets in; the mind becomes incoherent, and, although questions may still with some effort be answered rationally, yet the patient speedily lapses into his former condition, knitting his brows, tossing from side to side, withdrawing his hand from the attendant, muttering constantly, and falling gradually into a more unconscious state. Rigors generally occur early in the disease, and are always denotive of great danger. If effusion of serum, lymph, or pus take place to any considerable extent, convulsions and deep coma are sure to follow, soon terminating in death.

Countenance.—The state of the countenance is always a subject of inquiry with the intelligent practitioner. The mirror of the soul, it reflects, to a greater or less extent, alike the sensations of pleasure and of pain, of joy and of sorrow, and is thus capable of supplying important diagnostic indications in a great variety of diseases and accidents. To call attention to all the details which necessarily connect themselves with the study of the physiognomy under these circumstances, would be out of place in such a work as this, and I shall, therefore, content myself by referring to a few of the more frequent and conspicuous.

Excessive pallor of the countenance, especially of the prolabia, is generally denotive of great loss of blood, or of extreme shock of the nervous system. In the latter case it is often associated with a peculiar withered and shrunken expression of the features, reminding one sensibly of the decay of a leaf in autumn. In apoplectic affections of the brain, the face is turgid, flushed, and paralyzed on one side, thus causing serious distortion, the angle of the mouth being drawn to the opposite side, while the eyelid on the affected side has a drooping appearance, descending hardly half-way over the ball. In general inflammatory fever, whether the result of accident or of internal causes, the countenance is red and tumid, the eye is suffused, and the ala of the nose is rapidly dilated and contracted by the hurried inspiration. When the breathing is much embarrassed, as when there is deep congestion of the lungs, or mechanical obstruction to the entrance of the air, as

when a foreign body exists in the larynx or trachea, the face is livid and often remarkably puffy, particularly when the affection is of long standing, and accompanied by œdema of the subcutaneous connective tissue.   All painful affections of these organs are characterized by an anxious expression of the features, attended by an unusual dilatation of the nostrils during each act of inspiration, and by a peculiar heaving movement of the chest.   " In inflammation of the abdominal viscera," observes Dr. Marshall Hall, "attended with severe pain, the muscles of the face are in a state of continued contraction ; the features are unnaturally acute, the forehead is wrinkled, and the brows knit.   The nostrils are acute and drawn up ; the wrinkles, which pass from them obliquely downwards, are deeply marked ; the upper lip is drawn upwards, and the under one frequently downwards, so as to expose the teeth.   The state of the features is aggravated on any increase of the pain from change of position or external pressure.   When the abdominal pain arises from spasm, the muscles of the face are exceedingly contracted and distorted during the paroxysms of pain ; but in the intervals of the paroxysms the countenance assumes a calm and placid aspect."

The diagnostic value of the Hippocratic countenance has long been recognized by practitioners.   Its presence is always denotive of extreme danger, and is commonly associated with other symptoms of an untoward import, as twitching of the tendons, high delirium, a dry tongue, sordes on the teeth and gums, and excessive prostration.   It consists in a peculiarly sharp, retracted, and withered appearance of the features, and generally attends the closing scenes of all typhoid states of the system, whatever may be their cause or character.

Respiratory Organs.—The state of the voice often furnishes useful information respecting the nature of the lesions of the larynx and trachea.   Its peculiarity in croup is well known, being either sharp and shrill, like the crowing of a young cock, or low, hoarse, and almost extinct, especially if the disease has made considerable progress.   In œdema of the glottis, without being always hoarse, it is generally reduced to a mere whisper ; and in thickening of the vocal cords and ulceration of the mucous membrane of the larynx, partial loss of voice, and ultimately complete aphonia, generally attend.

The respiration should always be attentively examined.   In all acute diseases, attended with unusual vascular excitement, it is increased in frequency, short, and laborious.   In pneumonia and pleurisy it is generally diaphragmatic, the intercostal muscles being almost completely quiescent, with hardly any perceptible elevation and depression of the ribs. The patient, alarmed and anxious, breathes with great difficulty, dilating his nostrils at every inspiration, and raising the shoulders and upper part of the chest, so as to draw in as much air as possible at each effort.   In inflammation of the abdominal viscera, on the contrary, the diaphragm is nearly stationary, while the intercostal muscles are in full play, the act of inspiration being short and panting, lest the descent of the diaphragm should produce an aggravation of suffering by rudely compressing the affected organs.   In affections attended with cerebral congestion, effusion of blood, or depression of the skull, the breathing is slow, labored, and irregular ; often stertorous, and accompanied by a peculiar whiff.   In spasmodic diseases of the respiratory organs, the inspiration is quick and imperfect, as if the patient was unable to dilate the chest, and is usually accompanied with a characteristic wheezing sound, often audible at a considerable distance, during expiration, which is, at the same time, labored, and protracted.   Short, difficult, and anxious breathing, aggravated by muscular exertion, as in ascending a hill, or rapid talking, is generally denotive of hydrothorax, of solidification of the lungs, or of organic disease of the heart and great vessels.

Heart and Pulse.—The diagnostic signs manifested by the heart and arteries deserve careful consideration.   In examining the pulse, the exponent of the great central organ of the circulation, particular attention should be paid to its frequency, volume, and force, as these constitute the leading features by which the practitioner judges of the state of the system ; or, in other words, of the character and effects of the morbid action.   To do this properly requires not a little knowledge and experience, for nothing varies more than the condition of the pulse in health and disease.   Hence it is not surprising that it should have been pronounced by one of the ancient physicians to be the most fallacious of symptoms.

In traumatic fever the pulse, as a general rule, is quick, frequent, and hard, and similar qualities usually characterize it in idiopathic affections.   The increase in the number of its beats ranges from ten to thirty and even forty in the minute ; they are performed with a peculiar sharpness and rapidity, and the blood is sent into the arteries with such momentum as to cause their coats to rebound under the finger, offering thus a decided resistance to its pressure.   When this is the case, the pulse is said to be hard.   Hardness, quickness,

and frequency are often associated with fulness, especially in very plethoric subjects, laboring under intense inflammatory excitement; but such a coincidence is by no means always necessarily present; on the contrary, instances occur where the pulse is so exceedingly small and thready as to require some care to detect it. This is generally the character of the pulse in peritonitis, from whatever cause arising, and, therefore, it affords valuable diagnostic information. In certain affections of the brain, as in compression, whether a result of apoplexy or external injury, the pulse is slow, full, and laboring, as if the heart were oppressed by a heavy load which it is found difficult to carry or to shake off. The pulse after hemorrhage is strikingly peculiar, although it is not easy to define its character; it may be described as being very sharp, quick, and thrilling, as if the blood were sent into the artery with a kind of jerk, imparting thus a vibratory sensation to the finger. Once felt, it is impossible ever to forget it. An intermittent pulse is generally denotive of organic disease of the brain, or of the heart, lungs, or great vessels; sometimes, however, it appears to be the result altogether of functional disease, as dyspepsia, or gastro-intestinal irritation.

In examining the pulse with a view to its diagnostic value, it is to be remembered that it may be naturally slow or frequent, hard or soft, full or small, strong or feeble, depending upon idiosyncrasy, or the effects of previous or existing disease.

The time and mode of examining the pulse require some attention. As a general rule, the surgeon should not put his hand upon the wrist immediately after he has sat down by the side of the bed, as such a course would be likely to cause alarm, and thus lead to erroneous inferences. Nor should he use a watch for the purpose of counting it, especially if the patient is very sick and nervous, as this also might excite injurious apprehension. In fact, it is impossible to conduct the examination too carefully; for, unless this be done, the intention of the practitioner will often be completely thwarted, simply in consequence of his awkwardness. At least two fingers should be placed upon the radial artery, and the application should be continued sufficiently long to enable him to determine fully the character of its beats, particularly their frequency, volume, and power of resistance.

Kidneys.—The renal secretion should claim particular attention in every severe case of accident and disease. A very superficial inspection will generally at once detect remarkable deviations from the normal standard, both as it respects the color, quantity and consistence of this fluid, as well as any tendency it may manifest to the formation of deposits after having stood for some time in the receiver. But if a more thorough investigation be deemed necessary, as when organic disease of the kidney is suspected, or with a view to the detection of the existence of any particular calculous diathesis, a more minute and elaborate examination, conducted with the microscope and chemical tests, will be required; and it need hardly be added that such a procedure generally calls for an amount of knowledge, skill, and experience such as few professional men possess. As this subject will receive special consideration in the chapter on the urine and its deposits, no further allusion to it need here be made.

Finally the practitioner must not neglect to examine the state of the skin, noting particularly the character of its temperature, the presence or absence of moisture, the degree of its contractility, and any change of color it may have experienced; the condition of the limbs, as to the existence or non-existence of paralysis or injury; and, lastly, the state of the genital organs, if, upon inquiry, there is reason to suppose that they are either the seat of the morbid action, or that they deeply sympathize in the disorder of other parts of the body.

SECT. II.—MENSURATION.

An examination of the dimensions of a part occasionally affords valuable aid in determining the diagnosis of its lesions. Such a mode of investigation is particularly serviceable in fractures and dislocations, in coxalgia, and in affections of the chest, especially in pleuritic effusions, so common after accidents and disease.

The best contrivance for ascertaining the amount of shortening in an injured or diseased limb is the graduated tape, used by seamstresses and tailors, and inclosed in a metallic case, so as to admit of its being carried in the pocket. It is a yard in length, by half an inch in width, and being composed of oil-cloth it is perfectly inextensible, thus rendering it admirably adapted to the object. In order to attain perfect accuracy of result, it is necessary that the sound and affected members should be placed as nearly as possible parallel with each other; for if there is the slightest variation in their inclination it must proportionately impair the value of the examination, if not completely destroy it. Thus, for example, in trying to ascertain the amount of overlapping of the fragments of a broken

femur, the two thighs should be placed not only parallel with each other, but great care should be taken that they, as well as the buttocks, rest evenly upon the bed, table, or floor on which the patient lies. Finally, in order to perform the operation in the most unexceptionable manner, the additional precaution should be taken of maintaining the head, chest, pelvis, and extremities all in a straight line until the measurement is completed.

After the limbs and body have been adjusted as here described, two fixed points are selected, between which the tape is stretched. Thus, to take the thigh again as an illustration, the two proper points are the anterior superior spinous process of the ilium and the inner border of the patella. The distance between these two prominences having been ascertained upon the affected member, the tape is next stretched between the same points on the sound limb, the difference in the length between the two being the sum of the shortening of the injured bone. When no fixed points can be obtained, a mark may be made upon the skin, either with ink, iodine, or nitrate of silver. In trying to ascertain the precise amount of shortening in fractures of the extremities, especially the lower, we must not overlook the important fact, that there is in many cases, naturally, a marked difference in the length of the limbs, the disparity varying from a few lines to half an inch or even an inch.

The graduated tape may also be employed for measuring the diameter of a limb, as in disease of an important joint, or a suspected morbid growth. Or, instead of this, recourse may be had to the graduated compass of Mayor, which, however, notwithstanding its ingenious mechanism, really possesses no positive advantages over the tape. This instrument consists of four pieces, the central one, which is a flat rod, being marked by a scale of inches and lines.

Mensuration of the chest is often practised in pleuritic effusions, although such a means of diagnosis is seldom necessary in the hands of an intelligent and skilful surgeon, auscultation, percussion, and inspection being quite sufficient for the purpose in almost every instance that may come under his observation. When more than ordinary care is desired, the graduated tape, extending from the middle of the sternum to the centre of the spine, will readily supply the requisite information.

The plumb-line is occasionally used for determining the existence of curvature of the spine; such an expedient, however, can only be necessary in the earlier stages of the malady, before marked deformity has set in. When the disease is fully established, such a mode of investigation would savor alike of affectation and stupidity.

A ready method of determining the angle of on object, as, for example, that of a broken bone, has been suggested by Malgaigne. It consists in applying a sheet of paper, by its edge, to the limb so as to represent its vertical axis. At the point where the axis changes its direction, the paper is so folded as to follow it exactly; the result will be that the salient angle thus found will necessarily give the entering one caused by the fragments of the deformed bone. In order to determine the degree of this angle, a sheet of paper is folded in four, which " makes a right angle, or $90°$; folding again, one of the sides affords an angle of $45°$; adding this angle of $45°$ to the unchanged right angle, gives an angle of $135°$, and so on. Applying now this extemporaneous quadrant to the already ascertained angle of the fracture, we obtain without trouble, or loss of time, as accurate an estimate as possible."

SECT. III.—ATTITUDE OF THE PATIENT.

The attitude of the patient and the position of the affected part are variously and often remarkably changed in disease and accidents, and afford, in many cases, valuable diagnostic indications, not attainable in any other way. The study of the variations in the configuration of the body is of much greater moment, as a means of distinguishing different lesions, than is generally imagined, and has received less attention than its importance merits. In some affections, the diagnosis absolutely hinges mainly, if not entirely, upon the attitude assumed by the patient in consequence of the morbid action. We need only instance the peculiar distortion of the body in tetanus, caused by the continued and violent contraction of the muscles, drawing the trunk, in one case, powerfully forwards, in another backwards, and in a third to one side. No one that has ever witnessed this change of configuration can possibly mistake it in a similar attack; for there is no other lesion capable of producing it. In caries of the vertebræ, usually known as Pott's disease, and in lateral curvature of the spine, the result of irregular muscular action, the distortion of the body is characteristic. In coxalgia, the flattening of the hip, the elevation of the

pelvis of the affected side, the retraction of the heel, and the effacement of the femoro-gluteal crease are among the most valuable diagnostic signs of the malady.

In disease and injuries of the chest, the position of the patient is often highly characteristic. In inflammation of the lungs and pleura, attended with slight effusion, he generally lies on the affected side, or else upon his back, not on the sound side, as the weight and pressure of the diseased organ would seriously impede respiration and excite violent coughing. In hydrothorax, with large accumulations on both sides, the patient is obliged to raise his head and shoulders very much, or even to sit up in bed, in order to obtain the requisite supply of air. When he lies down, the effused fluid is diffused over a larger portion of lung, an occurrence which is instantly followed by increased difficulty of breathing, and by the necessity of a change of posture to prevent impending suffocation. "When out of bed, he is often observed to sit with the arms placed along the side, and the hands fixed and pressing forcibly on the chair or sofa on which he rests; in other cases he leans a little backwards, still supported by the arms and hands, which are pressed behind his back."

The attitude assumed by the patient in inflammation of the abdominal and pelvic viscera is generally very striking and characteristic. Unable to shift his position, he lies constantly upon his back, with his head and shoulders considerably elevated, the knees raised, and the thighs partially flexed, the object being to relax the abdominal muscles in the greatest possible degree, so as to take off their weight and pressure from the inflamed surface. In spasmodic affections, on the contrary, the position of the patient is altogether different; instead of observing dorsal decubitus, he lies at one time on this side and then on the other, now on the back, and next on the belly; and instead of avoiding pressure, he actually courts it, not feeling comfortable without it. Hence, he often doubles himself up, and twists and contorts his body in almost every possible manner, in order to obtain relief.

In stone of the bladder impeding the flow of urine, the attitude of the patient is frequently very singular. Sometimes he is compelled to assume a stooping posture; at other times he crosses or separates his legs, inclines his body to one side, lies down, rests on his elbows and knees, or lies on his back, and throws up his buttocks. In traumatic and other affections, attended with typhomania, retention of urine may be suspected if the patient lies on his back, with the limbs retracted. In acute inflammation of the kidney, the body is generally inclined a little forwards and towards the affected side, so as to relax the lumbar muscles, and take off any pressure they might otherwise exert upon the diseased organ.

The nature of an accident is not unfrequently revealed by the attitude of the part and body; sometimes by the one, sometimes by the other, and occasionally by both. Thus, the manner in which the patient inclines his head and supports his arm in fracture of the clavicle is so peculiar as to be absolutely, in great degree, pathognomonic of the nature of the lesion. Dislocations of the shoulder, hip, and other joints are denoted by striking, if not characteristic, changes in the attitude of the body and limb. The existence of a fracture is often revealed by a peculiar change in the conformation of the affected member, consisting either in a marked shortening, or in a peculiar alteration in the axis of the part. The disease called wryneck derives its name from the peculiar twist of the neck by which it is distinguished.

SECT. IV.—EXTERNAL CHARACTERS.

Important diagnostic data are sometimes furnished by the color, form, consistence mobility, pulsation, temperature, crepitation, sensibility, or odor of a part, and by the spots, scars, or ulcers upon its surface. A mere glance at these different topics will serve to show their value as means of distinguishing morbid action, whether it be considered simply in reference to its nature, or its nature and degree.

Thus, as stated under the head of inflammation, the *color* of the diseased part may be scarlet, as in inflammation of the mucous membrane of the fauces; lilac, as in sclerotitis; grayish or brick-colored, as in iritis. When the redness occurs in the form of a streak, extending up the arm or leg, it is denotive of phlebitis, or of angeioleucitis. Diffused discoloration characterizes erysipelas; circumscribed discoloration, boils and carbuncles. A scarlet hue implies great vascular activity, such as exists in acute inflammation; a purple hue, on the contrary, denotes partial stasis of the blood, which, if not soon arrested, may lead to gangrene.

Change in the *form* of a part may be caused by swelling, as in inflammation attended

with effusion, or it may depend upon the presence of a new growth, or it may be the result simply of hypertrophy. In fractures it is caused by displacement of the ends of the fragments; in dislocations, by the presence of the head of the bone in its new situation. In hernia, very striking changes generally attend the figure of the affected parts, especially when the protrusion is old and unusually bulky.

Extraordinary *consistence* of a part is indicative either of excessive induration from inflammatory deposits, particularly semiorganized lymph, or of the presence of a solid tumor, or a displaced bone. When the part is unusually soft, the alteration of consistence may depend upon the presence of pus, fluid blood, serum, or serum and lymph, and often requires the closest scrutiny for the successful detection of its precise character. Under such circumstances the history of the case frequently affords important diagnostic data, especially the age of the accumulation, and the presence or absence of inflammatory symptoms. If the part fluctuates distinctly, and is, withal, red, tender, or painful, the probability is that the alteration of consistence is due to the existence of pus; if, on the other hand, it is perfectly free from discoloration and uneasiness, although the undulation under pressure may be most perfect, the conclusion must be that the disease is either a chronic abscess, or else some serous or hematoid cyst.

The *mobility* of a part may be diminished or increased, thus throwing important light upon the nature of the case. As a general rule, it may be stated that it is lessened in dislocations, and augmented in fractures. The value of this symptom is well shown in diseases of the articulations, as well as in inflammation of other parts of the body, which, if at all seriously involved, have their mobility always proportionately diminished. In malignant tumors, loss of mobility of the morbid growth generally forms a prominent phenomenon in the advanced stage of the disease, in consequence of the firm adhesions that take place between it and the surrounding structures. A similar effect may be produced by the manner in which such tumors are bound down by the aponeuroses and muscles. In affections of the eye an alteration of the mobility of the iris often affords most important diagnostic information.

Abnormal *pulsation* in a part leads to the suspicion of the existence of aneurism, a suspicion almost converted into certainty, if, in addition to this phenomenon, there is a peculiar thrill, with a vibratory sensation, and a decided diminution of the volume of the part upon the application of pressure on the cardiac side of the artery supplying it with blood. The mere fact of the existence of abnormal pulsation should put the surgeon upon his guard, in order that, by redoubling his efforts at a thorough exploration, he may not commit any errors of diagnosis; laying open, perhaps, an aneurism, when he supposes that he is only dealing with an abscess or a hygroma.

The surgeon occasionally meets with what is denominated *crepitation*, a rough, grating, or friction sound, of great value as a diagnostic in fractures, emphysema, and inflammation of the sheaths of the tendons. In many cases it may be both felt and heard. In fractures it is produced by rubbing together the ends of the broken bone, and is generally so distinct as to be completely characteristic of the nature of the lesion. In order to elicit it, a good deal of management is often necessary; but in general it will be sufficient, after the ends of the broken bone have been fairly placed in contact, to grasp one piece firmly, and to hold it so while the other is rotated on its axis; or both fragments may be moved simultaneously in opposite directions.

The crepitation of emphysema is a kind of crackling sound, similar to what is produced by the rumbling of dry parchment, or by rubbing together numerous little dry, friable balls filled with air. The part, moreover, feels soft and puffy, and the contained air may be easily pressed from one spot to another.

Bony tumors of the antrum of Highmore and of the lower jaw, attended with great expansion and attenuation of their walls, occasionally emit, when pressed between the fingers, a peculiar crackling noise, similar to that of dry parchment. The sound thus elicited, however, is altogether different from crepitation, properly so termed, and its chief value consists in showing the alteration which the osseous tissue is capable of undergoing when it is subjected to long-continued, eccentric pressure.

The crepitation attendant upon inflammation of the sheaths of the tendons is altogether different from the two preceding varieties, resembling the sound caused by rubbing dry starch between the fingers. When the disease is chronic, it may sometimes be both heard and felt. It evidently depends upon the presence of plastic matter, and is most common about the wrist and ankle. This sound is often closely imitated in affections of the mucous burses, especially when they are considerably distended with fluid, intermixed with flakes of lymph and fibrinous concretions.

A faint crepitating sound is sometimes produced by breaking up the clots of a sanguineous cyst, and rubbing the fragments between the fingers. The noise, if any occur, is always most distinct at the base of the tumor, where most of the solid matter is necessarily collected.

An alteration of *temperature* in parts affected with disease is sufficiently common. and occasionally affords valuable diagnostic intimations. With what interest does not the surgeon watch the rise of heat in a limb after the ligation of its principal artery! A casual examination is generally sufficient for its detection; when more than ordinary nicety is required, recourse may be had to the thermometer. The intensity of the morbid action may sometimes be pretty accurately measured merely by observing the increase of its temperature. A sudden diminution of temperature, in a part previously in a high state of inflammation, may generally be regarded as an omen of unfavorable import, as it is denotive of the approach of gangrene.

An increase of the *sensibility* of a part is a frequent, if not an almost constant occurrence in disease, especially when acute. In ophthalmia, the slightest ray of light is a source of distress to the patient; in otitis, the ear is intolerant of sound; and in gastritis the stomach is oppressed by the smallest quantity of fluid, however bland, or however cautiously used. Parts, such as bones and ligaments, that are perfectly devoid of feeling in health, often become exquisitely sensitive in inflammation; and thus it is that the practitioner is not unfrequently enabled to detect the existence of morbid action in structures hidden from view, much better than he can in any other manner. The proper way of ascertaining the existence and amount of morbid sensibility is to make gentle and methodical compression, or to percuss the affected part, so as to communicate to it the vibrations of the whole hand, or, what is preferable, of one of the fingers.

When pain exists, a careful distinction should be drawn between that which arises from inflammation and that produced by spasm and neuralgia. In inflammation, the pain is steady and persistent, increased by motion and pressure, commencing with the morbid action, keeping regular pace with it, and gradually disappearing as the morbid action declines. In spasmodic affections, or colic, on the contrary, the pain is paroxysmal, or marked by distinct intermissions; abrupt, both in its invasion and departure; relieved by pressure, and change of posture, and generally attended with flatulence of the stomach and bowels. In neuralgia, the pain occurs in transient and violent paroxysms, darts along the course of the affected nerves with the rapidity of lightning, and is usually accompanied by more or less tenderness of the part, without any distinct tumefaction, discoloration, or augmentation of temperature.

Finally, there are certain affections which may sometimes be readily diagnosticated by a careful examination of the *cutaneous* surface, and that of the mucous outlets. Thus, if there are copper-colored eruptions upon the skin, excavated ulcers on the fauces, or tubercles upon the tongue, cheek, or lip, no one could fail to conclude that the system is laboring under a syphilitic taint. Partial or complete destruction of the uvula, tonsils, or arches of the palate, would inevitably lead to a similar inference, especially if, added to this, there is evidence of actual disease. Scars upon the cutaneous surface, scattered irregularly about, large, deep, white, and permanent, are generally denotive of the former existence of rupia.

The character of the ulcer will occasionally lead to the detection of its cause, or to the state of the system which has induced it. A girl, aged fourteen, was brought to the Clinic at the Jefferson Medical College, on account of a large chronic ulcer, of nearly one year's duration, seated in front of the leg, directly over the tibia; it was excessively painful, and had resisted a great variety of local and constitutional remedies. Having placed her under the influence of chloroform, I scraped away a thick mass of semi-organized substance which formed the bottom of the ulcer together with the carious and softened portion of the bone; and when she returned, a week afterwards, I was struck with the remarkable improvement that had taken place both in the part and system. Shortly after her visit, however, not less than five or six small unhealthy-looking ulcers, with thick, everted edges, and a foul, ugly surface, broke out around the old one, which by this time had also changed for the worse. Convinced that the disease was of a syphilitic nature, the patient was placed, without any further inquiry into the history of the case, upon the use of iodide of potassium and bichloride of mercury, under the influence of which, and of a nourishing diet, she rapidly regained her health and strength, with good sound cicatrices.

Absence of contractility in the *muscles*, whether dependent upon organic changes of their fibres, or upon loss of nerve power, is often very readily determined by electricity,

which thus becomes a most valuable means of diagnosis. In paralysis of the extremities, for example, if contraction be promptly provoked on the application of the electric current, it is evident that the integrity of the nervous connection of the limb with the spinal cord must be perfect, and also that the portion of the cord through which this connection is established is in a sound state, and conversely. The cause of the paralysis must be seated either higher up in the cord, in the brain, or in the muscular tissue, altered by disease, as the fatty or fibroid degeneration. In case of injury, as a bruise or wound, a similar test will determine the seat of the affection.

SECT. V.—THERMOMETRY.

Thermometry, as a means of diagnosis, is extensively practised in all cases of fever, whether traumatic, idiopathic, or specific ; its object, as the name implies, being to ascertain the amount of heat developed in the system during the progress of disease, and thereby determine the degree of the morbid action present in any given instance. The knowledge derivable from such an examination is not less valuable than the information obtainable from an examination of the pulse and of the respiration.

The normal average temperature of the body in the axilla, in the milder regions of the world, is about $98\frac{1}{2}°$ Fahr., from which it seldom deviates in health more than $1.8°$ to $3.6°$. Besides, any such departures are always very transient, whereas those occasioned by disease invariably continue so long as the morbid action exists. The temperature is heightened by exercise, reduced by sustained mental labor, and influenced by food, stimulants, age, temperament, habit, occupation, climate, the condition of the atmosphere, and other causes. It is liable to fluctuate during the twenty-four hours, and is usually at its maximum in the morning. The pulse and temperature in health usually rise synchronously, and every degree above $98°$ corresponds with an increase of ten beats of the pulse in the minute. Any persistent rise of the mercury above $99.5°$, or depression below $97.3°$ Fahr., is an indication of disease.

Unnatural heat cannot exist without fever, any more than fever can exist without abnormal heat. They are dependent the one upon the other. A patient may have a severe rigor, shiver, or feel icy cold, and yet the inner parts be inordinately warm, so that he may literally, as far as his sensations are concerned, burn and freeze at the same moment.

In pyemia the temperature is often very high, ranging from $106°$ to $108°$. There is, however, nothing very definite in this respect ; for observation has shown that, while in some cases and under certain circumstances, it is normal or nearly so, in others it presents remarkable variations, a sudden rise being often followed by a sudden decrease, and conversely. A temperature of $101°$ to $103°$ shows a mild disease, and one of $105°$ a grave one. In fever it ranges from $100°$ to $106°$. In low forms of this malady the hands and feet may feel cool, and yet the thermometer in the axilla may rise to $104°$. In acute rheumatism a temperature above $104°$ is always an alarming symptom ; and a similar remark is applicable to pneumonia. A rise of heat from $106°$ to $108°$, $109°$, or $110°$, is generally an indication of rapidly approaching dissolution. The highest rise of the thermometer before death has been noticed in tetanus and scarlatina. A persistence even of an inconsiderable degree of abnormal heat is an evidence of incomplete recovery ; and a recurrence of a high temperature during convalescence is a certain sign of an approaching relapse.

Fig. 119.   Fig. 120.

Thermometer.   Surface Thermometer.

Decrease of temperature is of great assistance in determining the prognosis of grave injuries and operations, a fall of one degree below the normal standard indicating depression, a fall of two degrees being an evidence of collapse, and a fall of from three to five degrees indicating algid collapse.

The thermometer usually employed for measuring the temperature in disease is the

one depicted in fig. 119. It is a very delicate, sensitive instrument, with a range of scale from 90° to 115°, and a subdivision of each degree into fifths. It may be furnished with a curved bulb for the sake of greater convenience in its application to the axilla, the situation generally selected for the purpose, as calculated to insure greater accuracy. The patient must have been in bed, well covered about the chest and shoulders, for at least one hour before the experiment is made. The instrument, previously a little warmed, is retained in the axilla, from which the perspiration has been wiped away, for ten minutes, at the end of which the rise or fall of the mercury must be carefully noted and recorded. The observations should be taken regularly every day twice, as nearly as possible at the same hour, either by the attendant himself, or by a trustworthy assistant, throughout the entire period of the sickness, the best time being between seven and nine o'clock in the morning, and between five and seven o'clock in the evening. The frequency of the pulse and of the respiration should be noted at the same time. In chronic cases, attended with occasional exacerbation, and also in acute attacks after the temperature has regained the normal standard, one daily observation made in the afternoon will be sufficient.

Important information in regard to deeply seated abscesses and rapidly growing tumors, particularly the small-celled sarcomas, may be derived from the use of the surface thermometer depicted in fig. 120. The temperature should first be taken over the seat of the disease, and then be compared with the temperature of the corresponding point of the opposite side of the body, the increase denoting the activity of the morbid action.

SECT. VI.—INSTRUMENTAL EXPLORATIONS.

There are certain affections the character of which can only be ascertained by a careful examination with the aid of instruments, full access to them in any other manner being impracticable. The instruments mainly required for this purpose are the probe, bougie, sound, speculum, stethoscope, and exploring needle, each of which will, therefore, demand some notice.

Probe.—The probe, fig. 121, is chiefly employed for the purpose of exploring fistulous tracks and sinuses, the course of balls, and the presence of foreign bodies. It may, therefore, be considered as a highly valuable instrument, one which is daily and hourly

Fig. 121.
brought into requisition by the surgeon in extensive practice. It is generally made so as to be flexible, being composed of silver or other suitable metal; and varies in length, diameter, and shape according to circumstances. The ordinary pocket probe is about five inches in length, and of the diameter of a crow-quill, one extremity being blunt, the other somewhat pointed, or furnished with an eye. For exploring the lachrymal passages a much more delicate instrument is required; the uterine probe, on the contrary, is very large; a long and rather stout instrument is generally employed for ascertaining the existence of a foreign body in the air-passages after the trachea has been opened, for tracing the course of a ball, and for exploring certain varieties of fistules and sinuses.

For detecting the presence of deep-seated balls, a probe, tipped with porcelain, has been advantageously used, as in the celebrated case of Garibaldi; and Mr. L'Estrange, of Dublin, many years ago invented what may be called a reverberating probe, an instrument provided with a little drum, consisting of a small circle of light wood, mounted on a stem which, secured to an ordinary probe, or sound, conveys to the ear, as well as to the finger, a more perfect idea of the nature of the material touched, whether muscle, bone, cloth, calculus, or metal, than any other contrivance.

Dr. L. A. Sayre, in 1871, devised what is now known as the vertebrated probe, fig. 122, consisting of a series of hollow silver disks, connected by a linked longitudinal chain, terminating in a square rod. The contrivance is particularly serviceable in the exploration of sinuous ulcers, in diseased joints, in flexions of the uterus, and in gunshot wounds, the small end of the instrument being, in the latter case, tipped with porcelain.

The *index finger*, if sufficiently long, and not too thick, is the best probe of all, as the information furnished by it is generally much more reliable than that supplied by a metallic instrument. It is particularly available in the examination of the vagina, uterus,

and rectum, whether the object be to detect the presence of disease, malposition, or the existence of an extraneous body.

The *rectal touch*, performed with the index finger, is constantly practised by the surgeon in sounding patients for stone in the bladder, with a view not only of ascertaining the presence of the foreign substance, but also of determining its size and situation. Enlargement of the prostate gland, and the existence of calculi in its substance, can seldom be satisfactorily diagnosticated in any other manner. Displacements of the uterus, pelvic tumors, and malformations of the internal genital organs, are often promptly detected by the rectal touch; and there is no practitioner that does not employ the finger in suspected disease of the anus and lower bowel. The rectal touch can readily discriminate between a hemorrhoidal tumor and a carcinomatous growth, a polyp, a prolapse of the mucous membrane, or a foreign body. The extent of the spasmodic contraction of the anus, which attends fissure of that outlet, is generally readily ascertained by the insertion of the finger.

The *vaginal touch* affords important information in relation to the diseases of the vagina and the uterus. It is in this manner that the practitioner ascertains the existence of the various kinds of tumors that are liable to form in these organs, whether benign or malignant, and also the different displacements to which they are subject. A practised finger will readily detect a carcinomatous ulcer of the uterus, a rent in the vagina, and a calculus in the bladder.

Whatever may be the instrument employed, it should be well oiled and warmed, to facilitate its introduction, and passed along in as gentle and easy a manner as possible. If the structures are inflamed and tender, it may be necessary, as a preliminary step, to lessen the sensibility by soothing measures, otherwise the procedure may be productive not only of severe pain, but of an aggravation of the disease. No general rules can be laid down respecting the position of the part or of the body during the examination, although it must be sufficiently obvious that this is a matter of paramount importance to a satisfactory result. In exploring fistulous tracks it is occasionally necessary to enlarge their orifice somewhat, in order to afford a more ready passage to the instrument or finger.

Bougie.—For ascertaining the condition of the mucous outlets of the body, as the urethra, œsophagus, and rectum, a bougie, which is but another name for a probe, is generally employed, the principle upon which the examination is conducted being the same as in exploring a part with a probe, properly so called; that is, the instrument, which is either straight or curved, and composed of gum elastic or metal, is well oiled and warmed, and then carefully introduced as far as the seat of the obstruction, the distance between which and the external orifice is now determined by looking at the graduated scale upon the surface of the bougie, or by making a scratch upon it with the nail. The examination is completed by insinuating the instrument gently into the stricture, so as to measure its extent and the degree of its resistance. The information thus elicited is generally of the greatest diagnostic and practical value.

Sound.—The instrument employed for exploring the bladder is called a sound, although it is in reality nothing but a probe, blunt-pointed at the distal extremity, and a good deal curved, so as to adapt it to the course and shape of the urethra. It is composed of steel, being perfectly smooth and of a round shape. Its object and mode of use will claim special attention in connection with the diagnosis of vesical diseases, which could not be established satisfactorily in any other way.

Speculum.—Of the value of the speculum as a means of diagnosis in affections of the vagina, uterus, anus, larynx, nose, and ear, it is unnecessary to say anything of a formal character, as it is fully appreciated by every intelligent practitioner. For the exploration of these passages, instruments of various forms and sizes are used, which will be particularly noticed under their respective heads. The uterine speculum, of which fig. 123 affords an illustration, was invented several thousand years ago, but had been entirely lost sight of until it was brought before the attention of the profession early in the present century by Recamier, of Paris, who thus conferred an inestimable boon upon the female sex by opening a new path to the treatment of her diseases. To impart perfection to such examinations a good light, either natural or artificial, is indispensably necessary.

Exploring Needle.—The value of the exploring needle cannot be too highly appreciated by the practical surgeon, as he is obliged to use it in the examination of a great variety

Fig. 122.

Sayre's Vertebrated Probe.

of external affections, the diagnosis of which does not admit of accurate determination in any other manner. On the other hand, however, there is reason to believe that there is no instrument, certainly none of its size, that is more frequently misapplied by the uninformed practitioner, or one which may do a greater amount of harm when used without

Fig. 123.
Speculum.

proper judgment and discrimination. Like everything else that is good, it is liable to abuse; a circumstance which cannot be too strongly impressed upon the mind of the young surgeon. I am sure I have seen immense injury, and even loss of life, produced by its careless and reckless use.

Numerous exploring needles are in the hands of the profession; some of which, displaying great delicacy and ingenuity, seem to combine all the advantages that such contrivances are capable of affording, while others are extremely clumsy, and, consequently, very imperfectly adapted for the purpose they are designed to fulfil. The great fault with most of them is that they are too large, thus inflicting an amount of injury upon the affected parts, which, especially in malignant diseases, is often followed by the most disastrous effects, causing, perhaps, not merely severe pain and hemorrhage, but such a change in the vital relations of the morbid growth as to lead to its rapid development, if not to the speedy destruction of the patient. I recollect seeing, some years ago, a tumor upon the hip of a lad, aged sixteen, which, after having been subjected to various examinations by highly respectable surgeons, was at length pierced with a large exploring needle. The swelling, which had been supposed to be nothing but a chronic abscess, and which for some time had been almost stationary, now rapidly increased in volume, ulcerated, and fungated, and in less than a fortnight destroyed life. Dissection showed that the morbid growth was a round-celled sarcoma, the activity of which had been greatly augmented by the changes induced in its vital relations by the injury inflicted by the instrument. A large volume might be filled with a rehearsal of the mischief that has been committed by the exploring needle in the hands of ignorant and careless practitioners.

Exploring needles consist either of a solid cylinder or of a species of trocar and canula, sharp-pointed, fine, and perfectly smooth, so as to facilitate their introduction and easy management. They are made of various lengths and diameters, according to the depth, volume, and nature of the part to be examined. The annexed cut, fig. 124, represents an exploring needle, with a lateral groove. The best instrument of the kind, according to my experience—one which answers every purpose in superficial affections, and which

Fig. 124.

Exploring Needle.

may always be used with the most perfect safety—is the ordinary cataract needle, spear-shaped, and sufficiently stout to prevent it from breaking. This is inserted into the most prominent portion of the tumor or morbid accumulation, with a kind of rotatory motion, the object being to condense, as it were, the edges of the opening to promote the escape of the contents of the swelling, which readily occurs, if they are of a fluid consistence, a drop of the liquid often adhering to the instrument, or resting upon the orifice of the little puncture. When the contents are of a semisolid nature, or the tumor is very deep-seated, the needle should be larger; or, what is preferable, it should be replaced by a very

small trocar, long enough to reach and penetrate the affected structures. Whatever instrument be used, it must not, on any account, be permitted to come in contact with any important vessels or nerves. When the swelling is of unusual bulk, it may be explored at several points of its extent at the same sitting. The little puncture made in the operation should immediately be closed with adhesive plaster or collodion. When the object is to exclude the entrance of air, the instrument may be carried some distance between the integument and the swelling, so as to make the opening somewhat valve-like.

A needle, perforated in its entire length, is occasionally used on the ground of its supposed superior efficacy in exploring deeply seated disease, its great value consisting in the facility of discriminating between different kinds of fluids, or in reaching deeply-seated fluids without the admixture of the superficial.

Kühn, Duchenne, Noeggerath, Hewson, Dresher, and others, have invented exploring instruments for the purpose of extracting a minute portion of a tumor, morbid deposit, or muscular tissue, with a view to a microscopical examination of its structure prior to an operation, the tube employed for this object being furnished with a peculiar contrivance attached to a sliding rod in its interior. Such a procedure, it appears to me, is more ingenious than useful, as its disturbing influence upon the morbid mass can hardly fail at least occasionally, to impart new life and energy to the affected tissues. It possesses, however, an actual value in trichinosis and certain forms of paralysis and muscular atrophy, inasmuch as it enables us to ascertain the precise condition of the muscular tissue, and determine whether any benefit will be likely to accrue from the employment of electricity and other curative agents. The most suitable instruments for such examinations are those of Duchenne and Noeggerath, depicted in figs. 125 and 126.

Fig. 125.

Fig. 126.

Syringe.—The use of the syringe occasionally affords valuable aid in the determination of the nature of a case. In suspected fistule of the bladder, rectum, and some of the other mucous outlets, the diagnosis may often be established, in the most unequivocal manner, in a few seconds, by the injection of a stream of water. Sometimes the fluid may be advantageously colored with indigo. A fistule of the neck, dependent upon organic stricture of œsophagus, may generally be promptly detected by making the patient swallow a liquid of this kind.

The ophthalmoscope, laryngoscope, rhinoscope, otoscope, and endoscope are of great service in the detection and treatment of diseases, difficult, if not impossible, to be reached in any other way. They all essentially consist of two mirrors for concentrating the light upon the object designed to be examined, and, as now constructed, are exceedingly simple, and, for the most part, easy of application.

The *ophthalmoscope*, devised by Helmholtz, who published an account of it in 1851, has been greatly improved by Loring, and is now a very perfect instrument, well adapted to fulfil the intentions of its ingenious inventor.

The *laryngoscope* owes its origin mainly to the genius of Czermak, of Vienna, by whom it was at once brought to a high state of perfection. It is designed, as the name implies, to assist in the explorations of the windpipe, and the only objection to it is the difficulty of its application, few practitioners being possessed of the requisite degree of tact to use it to advantage. The most valuable monographs upon the subject that have yet appeared, are those of Czermak, Turck, Semeleder, Stoerk, Voltolini, Mackenzie, Cohen, Gibb, and Moura-Bourouillon.

The invention of the *rhinoscope* was a necessary consequence of the application of the

laryngoscope in the hands of its distinguished inventor. In exploring the windpipe, it was easy to see the upper part of the pharynx, the orifices of the Eustachian tubes and the posterior nares, and thus arose what may very properly be called the science of rhinoscopy.

To Mr. Toynbee, of London, belongs the merit of introducing an instrument called the *otoscope*, which is of great aid in the examination of the ear, with a view of determining its precise condition in cases of supposed disease. It is of very simple construction, as well as of easy application.

The *endoscope* is employed chiefly for exploring the urethra and the bladder, although it may also be advantageously applied to other canals, as the rectum, vagina, uterus, nose, larynx, pharynx, and ear. It is a contrivance of recent invention, brought to a remarkable degree of perfection by the ingenuity of Desormeaux, Cruise, and other observers. The endoscope of the Dublin surgeon is, in principle, identical with that used in 1824 by Dr. Fisher, of Boston. It consists simply of a tube or speculum, which is inserted into the cavity to be examined; of a mirror of polished silver, perforated at the centre, and placed at an angle of about $45°$; and of a plano-convex lens, of suitable focal length, for concentrating the light.

The use of the *stethoscope*, as a means of surgical diagnosis, is comparatively limited, and it might be altogether dispensed with by those who have a well-practised ear, and are not averse to the employment of immediate auscultation, or the direct application of the ear to the affected parts. Lisfranc thought the stethoscope might be advantageously resorted to for the purpose of detecting crepitus in deep-seated fractures; or, what is the same thing, in fractures covered by a large amount of muscular and other tissues, as, for example, those of the neck of the thigh-bone in very fleshy subjects. Few occasions, however, arise in which such a mode of exploration can be of any real service, and I am not aware that any of our more experienced practitioners ever employ the instrument with this object.

Laennec, in the early part of the century, proposed auscultation as a means of detecting the presence of calculi in the bladder. He thought that it would be particularly serviceable in ascertaining the existence of very small concretions, which, when struck with the sound, emit only a very indistinct noise; and he suggested that, under these circumstances, the stethoscope should be applied to the pubic or sacral region while the instrument is freely moved about in the organ. The recommendation, however, has not met with any particular favor, and there are, I suppose, few surgeons who would feel inclined to cut a patient for stone on such slender evidence of its presence.

The chief value of auscultation, then, is restricted to the examination of diseases of the heart, pericardium, lung, and pleura; and to the investigation of certain lesions of the abdomen, uterus, and ovaries, simulating pregnancy, with a view to the detection of the fœtal circulation. Dry tapping, as it has emphatically been called, would probably be of much less frequent occurrence, if the stethoscope were oftener employed in supposed dropsy in young, unmarried females.

SECT. VII.—EXAMINATION OF THE DISCHARGES.

The discharges, normal and abnormal, from different parts of the body, often furnish the surgeon important diagnostic information. Thus, an habitual flow of tears over the cheek is usually denotive of disease of the lachrymal passages, and necessarily suggests the propriety of a careful examination of them with a view to the detection of obstruction. For a similar reason the surgeon is prompted to inspect the ear in otorrhœa, and the nose when it is the seat of muco-purulent profluvium. The very nature of the discharge informs him of the existence of inflammation, but how that inflammation is produced, whether by the presence of a foreign body, a piece of dead bone, or a polyp, is a question which can only be decided by the most careful scrutiny; requiring, perhaps, the employment of the syringe to wash away the secretion, and repeated inspection before the precise nature of the case can be satisfactorily made out. One of the most important symptoms of inflammation of the maxillary sinus is a flow of pus into the throat; but no surgeon can be certain that it proceeds from that cavity unless he has previously ascertained that there is no disease of the mucous membrane of the nose.

The character of the *sputa* has long been an object of study with practitioners, on account of the useful information which they afford in regard to the existence of particular diseases. Such information is hardly of less value to the surgeon than to the physician, as it apprises him of the presence of lesions which forbid surgical interference, or places

him in possession of useful data respecting the occurrence of pulmonary complications, so common after accidents and capital operations. The reddish streaks in the expectoration excite suspicion of the existence of pneumonia; the rust-colored sputa confirm that suspicion, and at once invest the case with its proper importance. The fetid, putrilaginous matter coughed up in gangrene of the lungs is characteristic of that disease, from whatever cause proceeding. In phthisis, after the occurrence of caverns, the expectorated matter is ejected in distinct, rounded masses, with irregular and indented edges; it sinks in water, and is of a yellowish color, with various shades of ash and even green, and streaked with opaque specks. A discharge of blood by vomiting is denotive of hemoptysis when the fluid is of a scarlet color, and of hematemesis when it is perfectly black. In affections of the throat, attended with thick, mucous or muco-purulent secretion, the sputa are sometimes streaked with blood. The saliva in mercurial stomatitis has a characteristic odor, and the same is true of the discharge which accompanies gangrænoris.

A thick, yellowish discharge, more or less abundant, from the *vagina*, is indicative of inflammation of that canal, of the uterus, or of both, and the addition, of blood may usually be regarded as an evidence of concomitant ulceration. In a chaste woman such a profluvium is generally to be considered as the result of accidental causes; in the courtesan, on the contrary, it at once awakens suspicion of the existence of gonorrhœa or chancroid. In carcinoma of the womb, the disease is attended, in its earlier stages, by hemorrhage, and afterwards, when ulceration has set in, by a foul, purulent, or sero-sanguinolent discharge, more or less copious, and so excessively fetid as to indicate unmistakably the character of the lesion.

In the male, a discharge of matter from the *urethra* generally furnishes useful information respecting the character of the disease under which the individual is laboring. When the discharge is thick, yellowish, and abundant, it is denotive of gonorrhœa, or chancre, though in the latter case it is seldom very profuse; when thin and lactescent, or like the white of an egg, it indicates the existence of gleet, or prostatorrhœa. A large and sudden discharge, especially when no profluvium precedes or follows it, is to be taken as an evidence of spermatorrhœa.

The presence of *spermatozoa* in hydrocele sometimes throws important light upon the source of the water. It has been ascertained that whenever the fluid contains cells of this kind, the disease is generally of an encysted nature; for, although they also occur in ordinary hydrocele, yet the circumstance is so uncommon that it must be regarded as altogether of an exceptional character.

Of the signs afforded by the *renal* and *urinary secretions*, as evidences of disease, either of a local or general character, proper mention will be made in the chapter on the affections of the urinary organs. Here I shall only add that a careful examination of these secretions is often a matter of the greatest importance to the surgeon, especially when he is obliged to decide respecting the propriety of a severe operation, the result of which might be seriously compromised by the existence of organic lesion either of the kidneys or of some other important viscera. Hardly any man, however reckless, would attempt such an undertaking if the urine were loaded with albumen and renal casts.

The existence of disease of the *anus* and rectum, and even the true nature of such disease, may often be satisfactorily inferred by the discharges furnished by these parts. A flow of pure blood, especially during defecation, is generally denotive of internal hemorrhoids; so also if there are frequent evacuations of thick, bloody mucus, either while the person is at the water-closet, or in the intervals of his visits. A narrow, compressed, or flattened state of the feces is indicative of mechanical obstruction, occasioned either by stricture of the rectum, enlargement of the prostate gland, or contraction of the anus. In ulcerated carcinoma of the lower bowel, the discharges are generally very profuse, of a muco-purulent nature, mixed with blood and mucus, and excessively fetid; in fact, characteristic of the nature of that horrible malady.

The matter of certain *abscesses* serves to point out their nature and situation, or their accidental communication with neighboring parts. Thus, in the mammary gland, the fluid may contain milk; in the liver, bile; in the kidney, as when an opening takes place externally, urine. Abscesses of the wall of the abdomen have been known to contain biliary calculi; of the joints, fragments of cartilage and bone. In acute abscesses, the contents are thick and yellowish; in chronic, or strumous, thin and slightly greenish, with an intermixture of small opaque, whitish flakes, resembling grains of boiled rice.

The discharge accompanying *ulcers* generally affords valuable hints respecting the

nature of their action.   Healthy granulating ulcers or wounds always yield a thick, yellowish pus, possessing all the properties of laudable pus, as described under the head of suppuration ; when, on the contrary, their action is unhealthy, the discharge is thin and bloody, ichorous, sanguinolent, and more or less irritating.   In carcinomatous ulcers, the discharge is generally profuse, foul, devoid of pus globules, and excessively fetid. In ulcers of the bones, it is ichorous and irritating ; never healthy, so long as there is any diseased osseous tissue.

The *odor* emitted by a part in a state of disease sometimes supplies important data for the diagnosis of a case.   Most readers are familiar with the remarkable anecdote related of J. L. Petit.   Travelling through Germany, this celebrated surgeon, while stopping at an inn to change horses, was struck with the odor of gangrene, which he distinguished from several others, hardly less offensive.   Not understanding the language of the country, he made his wishes known to a female, who showed him into an adjoining room, where he found a man apparently moribund from a mortified intestinal hernia.   Happy in being able to render him some assistance, he carefully dressed the parts, and meeting, before he set out upon his journey, with a French physician, he instructed him in the future management of the case.   Upon his return, five months afterwards, he had the gratification to learn that the man had completely recovered his health without a stercoraceous fistule.

The odor attendant upon ozæna is characteristic ; no one that has ever perceived it can mistake it.   The contents of an abscess at the verge of the anus always emit a fecal smell ; a peculiar fetor accompanies the formation of a urinary fistule, and no one can be deceived by the odor of the breath in salivation.   In hospital gangrene the stench is so remarkable that, once noticed, it can never be forgotten, although it is so unlike everything else of the kind as to render it impossible to define or describe it.   The odor which accompanies gangrene of the mouth of children is unmistakable.   The diagnosis of ulcerated carcinoma of the uterus may often be established by the sense of smell alone.   Large wounds in a state of profuse suppuration not unfrequently exhale a peculiar nauseous or sickening odor, in some degree characteristic of the attendant action.   The pus of a scrofulous lymphatic gland, for a long time pent up, is sometimes horribly fetid.   A smell, similar to that of a macerating tub, often attends abscesses depending upon caries of the spine. In all these cases, as well as in many others that might be adduced in illustration of the subject, it is probable that the peculiarity of the odor is due partly to the admixture of the natural secretions of the affected structures.

CHAPTER XIV.

MINOR SURGERY.

Minor Surgery comprises an account of some of the more common instruments used in surgery, of the mode of making incisions, or of performing the elementary operations, the establishment of issues, the introduction of the seton, the application of the actual cautery, bleeding, and the art of bandaging and of dressing.   As some of these topics have already been incidentally discussed, especially in the chapter on inflammation, I shall here confine myself to the consideration of those that have not yet been touched upon in previous parts of the work.

SECT. I.—INSTRUMENTS.

Instruments are as necessary to the surgeon in the execution of his operations as they are to the mechanic in the performance of his daily labor.   But as the best workman employs the fewest tools, so the best operator employs the fewest instruments ; and to the man of science and taste nothing is more disagreeable than an ostentatious display of such material.   A few articles, well selected, and kept in proper order, ready to do their work at the shortest notice, are all that any surgeon really requires for the successful performance of nearly every operation that he may be called upon to undertake.   The simplicity of his armamentarium often affords a better idea of his skill and science than the most daring feat upon the operating table.

The elementary and really important instruments are very few in number; they are the scalpel, needle, saw, forceps, probe, and director, which are the parents of nearly all the numerous and diversified surgical contrivances found in the shops of the modern cutler. With a little modification the scalpel is converted into the bistoury, the lancet, and the amputating knife, and may thus be made to answer all the purposes required of a cutting instrument. The same needle with which a suture is made, may, with a little difference of size and shape, be readily used for couching and lacerating a cataract, or inserting a seton. The saw may be modified without limit, and the same is true of the forceps, whether intended for dissection, dressing, or the division of bone. The probe, which, from its great usefulness, may almost be regarded as another finger, varies in size and shape, from the little delicate, almost thread-like instrument devised by Anel for examining the lachrymal canal, to the sound employed by the lithotomist for exploring the condition of the bladder. The grooved director, which serves to guide the knife in the division of the soft parts, as in operations for hernia, impermeable stricture, and stone in the bladder, is, in fact, nothing but a modification of the ordinary probe.

The *knives* generally in use among surgeons for the more ordinary daily operations are the scalpel and bistoury, of various sizes and shapes, so as to adapt them to the exigencies of each particular case. All such instruments should have a tolerably large handle, and I decidedly prefer one that is somewhat rough, as being less likely to slip from the fingers when wet with blood. The blade should be rather long and slender, gradually tapering to a point, which should be quite sharp, or, at any rate, not at all rounded. In some operations, a double-edged, spear-shaped knife is very serviceable, as in the extirpation of

Fig. 127.   Fig. 128.   Fig. 129.   Fig. 130.   Fig. 131.   Fig. 132.
tumors, and the extraction of cataract. Finally, it is sometimes advantageous to have a knife the handle of which terminates in a semisharp steel edge. Such an addition is occasionally of great use in the excision of morbid growths. The above figures afford a good idea of the more common of scalpels.

Fig. 133.

The *bistoury* differs from an ordinary scalpel chiefly in being longer and more slender; it may be straight or curved, with a sharp or blunt extremity. It is often made so as to

open and shut like a penknife, as in fig. 133; but the best instrument of the kind is one with a fixed handle. The term bistoury has been supposed to be derived from Pistorium, the name of a town where it was at one time extensively manufactured. Particular forms of this instrument, invented for particular operations, will be alluded to in different parts of the work.

The adjoining sketches afford good illustrations of the ordinary forms of the bistoury: fig. 134 represents the sharp-pointed instrument, and fig. 135 the probe-pointed.

Fig. 134.

Fig. 135.

There is hardly any operation in which it is not necessary to use *forceps*. The instrument usually employed is the common dissecting-forceps, represented in fig. 136. In some cases, as when the object is to pinch up a delicate structure, as the conjunctiva, or

Fig. 136.

a very thin layer of fascia, a pair of forceps provided with a small tooth, as represented in fig. 137, will be found not only very convenient, but almost indispensable.

Fig. 137.
Scissors are essentially nothing but two knives united by a screw, and furnished each with a ring-handle; if thin, and properly sharpened, they divide the tissues with little or no contusion, and may be employed for a great variety of purposes. They are particularly valuable in many of the more delicate operations upon the eye. They may be straight or curved on the edge or on the flat, pointed or blunt at the extremity, or one blade may be sharp and the other blunt. The rings should always be large for the ready accommodation of the thumb and finger. Figs. 138 and 139 exhibit the two principal forms of surgical scissors.

Fig. 138.
For holding the flaps out of the way in performing certain operations, especially such as involve the removal of morbid growths, among the more deep-seated structures, or the exposure of arteries, instruments, called *retractors*, are often of great service, and should

find a place in every well-arranged operating case. The best instruments of this kind are made of flexible metal, mounted upon handles.

Fig. 139.
For holding and pulling out morbid growths, such as deep-seated tumors of the neck or thigh, and for drawing down the cervix of the uterus in operating for vesico-vaginal fistule, as well as for other purposes, a Museux's forceps, shown in fig. 140, or a common

Fig. 140.
volsella, is of great use. The teeth being plunged into the morbid mass, the instrument is either held by the surgeon himself, or the requisite traction is exerted by an assistant.

Fig. 141 represents another contrivance, which may be used for a similar purpose, its prongs being firmly screwed into the substance of the morbid growth.

Fig. 141.

The forceps shown in fig. 142 are very serviceable in the extirpation of large tumors of the uterus, in grasping, holding, and pulling down the morbid growth. Their mode of action is apparent at a glance.

Fig. 142.
